PREFACE TO THE SECOND EDITION

The numerous advances in our knowledge of diseases of the heart since the first edition of this book have necessitated extensive rewriting of almost every chapter. However the basic objectives and the form of presentation of the first edition have been preserved.

A section of three chapters devoted to graphic methods of examination has been added because of the many recent contributions to this field.

Major sections of this revision have been devoted to cardiac surgery. New techniques of direct vision surgery such as inflow stasis, hypothermia, cross circulation, external shunts and pump-oxygenators, and the results of their clinical application have been included. The availability of surgical therapy for certain cardiac lesions has imposed new responsibility on the physician. Accordingly, appropriate presentations have been made of the application of the various diagnostic techniques, the interpretation of findings, the indications for surgery and especially the risks and results thus far obtained with available surgical procedures.

Extensive revisions and additions have been made to the sections on treatment other than surgical, throughout the book. These include among others the discussions of treatment of congestive heart failure particularly intractable heart failure, the discussions of digitalis, quinidine, Pronestyl and mercurial diuretics, the use of oral diuretics, very low sodium diets, resins, the induction of hyperchloremic acidosis with Diamox and ammonium chloride to potentiate the mercurial diuretics, the use of radioactive iodine in the treatment of intractable angina pectoris and intractable heart failure as well as of thyrocardiac disease, a discussion of the host of drugs that have been used in the treatment of angina pectoris, prophylaxis against rheumatic fever by the treatment and prevention of Streptococcus A (hemolyticus) infections, the treatment of rheumatic fever with corticosteroid hormones and the possibility of preventing cardiac damage, the modern antibiotic treatment of bacterial endocarditis including short term therapy, the control of tuberculous pericarditis with antituberculous drugs and the treatment of pulmonary (respiratory) and cardiac insufficiency in cor pulmonale according to the underlying pulmonary disease. The discussion of the treatment of acute myocardial infarction has been expanded particularly because of a more detailed consideration of the controversial questions of the use of anticoagulants, bed rest versus chair rest and the effectiveness of the vasopressor drugs in the treatment of shock. A number of new anticoagulants have been discussed as well as the use of Mephyton to control excessive hypoprothrombinemia or bleeding. The chapter on hypertensive heart disease has been greatly enlarged, partly because of the discussion of therapy, especially of the various newer hypertensive drugs.

The chapters on coronary atherosclerosis, congenital heart disease, chronic pulmonary heart disease have been greatly expanded. Extensive revisions or additions have been made in regard to the following subjects among others: the pathophysiology of cardiopulmonary disease, lung volumes and tests of pulmonary function, the viscoelastic properties of the lungs, the work and force of breathing, the relation of lipids and lipoproteins of cholesterol metabolism, of cholesterol and fat intake and of sex hormones to coronary atherosclerosis, cardiac arrest, the use of cardiac massage, defibrillation, the external cardiac pacemaker and defibrillator, Starling curves of cardiac function, vectorcardiographic findings in cardiac hypertrophy, bundle branch block and myocardial infarction, extracellular and intracellular electrolytes and electrolyte disturbances in congestive heart failure, recent contributions to the theories of the arrhythmias and Wolff-Parkinson-White syndrome, the varieties of syncope, diagnostic tests for pheochromocytoma, revised criteria for the early diagnosis and treatment of bacterial endocarditis and hyperserotoninemia.

My indebtedness is acknowledged to my colleagues on the Attending and Resident Staff of The Mount Sinai Hospital, New York, for the knowledge gained in many fruitful discussions, to various members of the Cardiographic Department and of the Catheterization Group for their aid in obtaining additional illustrations and to members of the Library Staff for assistance in obtaining medical journals To my wife without whose help this revision could not have been completed, I am indebted for aid in the preparation and reading of the manuscript, for typing my often illegible revisions, for checking the revised bibliography and its accurate reflection of additions and deletions in the text, for finding lost page numbers initials and even authors, for proper changes in the order and numbering of the bibliographic references and typing them, for reading the galley and page proof and for rearranging and typing the new index To my publishers The W B Saunders Company, I am grateful for their encouragement and cooperation

CHARLES K FRIEDBERG

New York City,

PREFACE TO THE FIRST EDITION

This book endeavors to provide a comprehensive and integrated exposition of the diseases of the heart The swift pace of recent advances in this subject calls for a reorientation in presentation, and a modification in emphasis from that found in available standard works on cardiac disease

In particular, special emphasis has been placed on the pathologic physiology of cardiac disorders, including the pathogenesis or mechanism of the symptoms and signs of circulatory failure, of angina pectoris and myocardial infarction and of the various manifestations of the individual cardiac diseases These discussions are not exhibited for mere academic consumption, but with the belief that an understanding of the dynamic events responsible for clinical phenomena is essential for maximum skill in diagnosis and treatment

The increased utilization of quantitative measurements in the clinical study of circulatory disease is reflected in detailed discussions of the cardiac output, blood volume and extracellular volume peripheral and intracardiac blood oxygen concentration and intracardiac pressures, body fluid and tissue electrolytes, and renal and pulmonary blood flow Throughout the book these measurements are applied to clinical understanding and practical usage in the every-day diagnosis and treatment of cardiac disease

Certain subjects of predominant importance have been presented as individual monographs Ten chapters have been devoted to circulatory failure, eight chapters to diseases of the coronary circulation and three to rheumatic fever and rheumatic heart disease Bacterial endocarditis has been discussed extensively because it is the most frequent curable cardiac disease Its bacteriological aspects have been presented in some detail because of their importance for effective diagnosis and treatment Congenital heart disease has likewise been fully described because of the many recent advances in diagnosis and treatment Special recognition has been given to cardiac catheterization, oxygen and pressure studies and angiocardiography as aids to the exact diagnosis essential for possible surgical treatment The diagnosis and treatment of other remediable cardiac conditions have been emphasized, e g , thyrocardiac disease, constrictive pericarditis and heart failure due to anemia avitaminosis arteriovenous aneurysm and myxedema Reference is also made to very recent advances in the surgical treatment of various clinical and experimental cardiac lesions including coronary artery disease valvular disease and septal defects as well as other congenital anomalies tumors and traumatic disturbances To avoid repetition, no special chapter is devoted to cardiovascular emergencies, but appropriate discussions may be found rapidly by reference to the individual conditions under the heading "emergencies, acute cardiovascular in the index

Certain less common forms of cardiac disease have been described in greater detail than is usually found in standard books, e g cardiac disease related to endocrine, metabolic and nutritional disturbances, including also the cardiac effects of hemochromatosis von Gierke's disease xanthomatosis, amyloidosis and acute porphyria Ample consideration has been given to the effects of various infections on the heart to nonspecific myocarditis and to other myocardial diseases of obscure origin, e g idiopathic hypertrophy scleroderma and myotonia atrophica

Roentgenology and electrocardiography have become essential elements of cardiologic practice and are thoroughly discussed throughout the book Individual chapters devoted exclusively to a formal presentation of electrocardiography and roentgenology have been omitted partly to avoid duplication and save space but chiefly because as isolated subjects they could not be presented adequately in single chapters Instead emphasis has been placed on the application of electrocardiographic and roentgenologic interpretation to clinical practice, in which these findings mi

be integrated with the clinical history, symptomatology and other objective data

Electrocardiography has been discussed in detail in connection with the arrhythmias, angina pectoris, myocardial infarction, pericarditis and myocardial disease, while both electrocardiography and roentgenology including angiocardiography have been amply considered in connection with such subjects as chamber enlargement, valvular heart disease and congenital cardiac lesions To a lesser extent electrocardiographic and roentgenologic findings are also described in connection with almost every other type of heart disease, according to the importance and diagnostic value of these findings relative to other clinical features A number of other graphic methods, including phonocardiography roentgenkymography electrokymography (fluorocardiography) and endocardial electrocardiography, have recently received increasing attention from cardiac investigators and these have been briefly mentioned when pertinent However, because of their limited practical value at the present time these and other subjects in which the author may have a special interest have not been unjustly emphasized

It is impossible to make specific acknowledgment to the host of individuals who directly or indirectly have helped provide the knowledge which is the basis for this book I owe much to hospital colleagues and associates, and especially to Dr Arthur Fishberg Of the numerous teachers and collaborators to whom I am indebted I wish to mention specifically the late Dr C J Rothberger of Vienna who trained me in experimental cardiology and electrocardiography, the late Dr Louis Gross in cardiac pathology and the late Dr Emanuel Libman in clinical cardiology

For the opportunity of studying and utilizing the clinical material on his wards and for his encouragement in clinical research, I am especially grateful to Dr George Baehr I also wish to offer thanks to Dr B S Oppenheimer and Dr I Snapper, under whom I have served for brief periods Dr A Master kindly permitted my use of the electrocardiographic files and Dr M Sussman permitted the use of the roentgenologic files of The Mount Sinai Hospital I am grateful to Drs A Grishman and Joan J Lipsay for their assistance in choosing most of the material for illustrations and to Drs J B Schwedel and R H Marshak for isolated roentgenograms To my wife I am indebted for typing the original manuscript and its several revisions, for editorial assistance and especially for her tolerance during my writing of this book

The editorial and administrative staffs of my publisher the W B Saunders Company, have been helpful and cooperative

GRAPHIC METHODS OF CARDIAC EXAMINATION

Chapter 1

ROENTGENOLOGIC EXAMINATION OF THE HEART

Roentgenologic examination of the heart is one of the major diagnostic techniques in clinical cardiology and is essential for complete cardiac evaluation. Not only does it provide an accurate outline of the projected cardiac borders but it reveals also the volume of the heart and its vascular extensions, the relative size of the individual chambers, the character and extent of the cardiac pulsations and the presence of intracardiac or pericardial calcification. By rotating the patient the examiner may view the heart from every angle. Permanent objective records of the cardiac silhouette and the pulsations of its borders may be made on films or tracings. Serial records at varying intervals may reveal significant changes in size, contour or pulsation of the heart and thus provide useful information as to the course and progression of various cardiac diseases.

ROENTGENOLOGIC TECHNIQUES

The roentgenologic techniques most commonly employed in examination of the heart are fluoroscopy and teleoroentgenography or orthodiagraphy. But in special instances or for research purposes these are supplemented by angiocardiography, kymography or electrokymography, tomography (planigraphy), cinematofluorography and volumetric reconstructions. Technical details can be mentioned only briefly in this chapter and the reader is therefore referred to the excellent monographs of Assmann,[2] Vaquez and Bordet,[20] Zdansky,[illegible] Roesler,[illegible] Laubry et al.[illegible] and Schwedel.[illegible] The anatomic basis for the roentgenologic silhouette of the heart is presented in a monograph by Koch and Weck.[illegible]

FLUOROSCOPY

This permits direct and continuous roentgenologic examination of the heart. The examiner is in front of the fluorescent screen and the patient behind the screen, between the screen and the x-ray tube. The screen and tube are rigidly connected and move as a unit. By varying the horizontal and vertical dimensions of the aperture one may alter the size of the image on the screen so as to view the entire chest or to concentrate on small areas. Because of the proximity of the patient to the tube, the roentgen rays diverge considerably and thus exaggerate the size of the heart. Therefore fluoroscopy is not used for exact measurement of the cardiac dimensions, but it provides a sufficiently accurate approximation to permit the recognition of generalized or chamber enlargement, as well as alterations in the pulsations of the heart and great vessels. Various devices have been suggested to correct for fluoroscopic enlargement of the true cardiac size.[7] The silhouette is studied not only with the patient facing the screen (posteroanterior position) but also in various degrees of rotation, especially in the right anterior oblique and left anterior oblique positions,[12] which will be described below. Because of the simplicity, convenience and economy of fluoroscopy, this technique has become a routine part of the cardiac examination in the physician's office as well as in the clinic or hospital.

Fluoroscopic examination is often conducted while the patient swallows a thick solution of barium sulfate in order to determine more clearly enlargement or abnormal pulsation of the left atrium or of the aorta. Anomalies of the aortic arch may be disclosed by their effect on the barium-filled esophagus. Fluoroscopy is used to facilitate the passage of a cardiac catheter and to localize the position of the catheter tip. It is the basis of the technique of electrokymography (fluorocardiography).

Cinematofluorography is the technique of recording the image on the fluoroscopic screen by photography.[3, 16] A method has also been

developed to obtain three dimensional visualization of cinefluorographic films by the use of two synchronized x ray tubes [17]

It is essential that the physician engaging in fluoroscopic examinations should be mindful of the hazards of roentgen ray exposure These dangers may be minimized by limiting exposure to the briefest possible duration This in turn requires maximal accommodation (dark adaptation) of the examiner The area of exposure is reduced by apposing the screen to the chest wall and by narrowing the aperture The examiner should be protected by the use of a leaded screen, chair apron gloves and goggles

TELEOROENTGENOGRAPHY

An x ray film (roentgenogram) of the chest is taken at a standard distance, usually 2 meters or 6 feet At this distance the x rays are much less divergent than at the close range of fluoroscopy and the degree of exaggeration of the size of the cardiac silhouette is usually not more than 5 or 10 per cent Usually a film in the posteroanterior position is taken with the patient's anterior chest wall in contact with the film containing cassette and the roentgen ray tube centered at the level of the sixth thoracic vertebra Other views may also be filmed corresponding to those mentioned under fluoroscopy Because of variations in the cardiac silhouette with respiration and motion of the diaphragm the same standard exposures are made, usually at the end of a normal inspiration For more accurate research studies the exposure may be synchronized with systole and diastole

ORTHODIAGRAPHY

In order to avoid the exaggerating effect of divergent x rays and thus obtain more accurate measurement of heart size, only the central parallel rays of the x ray tube are used in orthodiagraphy The fluoroscopic screen is fixed and the patient stands behind the screen The aperture is narrowed so as to leave a very small square slit through which the x rays cast an image on the screen The tube and aperture are moved together along the outlines of the chest wall diaphragms and cardiac chambers on the fixed screen The examiner rapidly traces these outlines by pencil or crayon on transparent paper attached to the front of the screen The slightly greater accuracy permitted by this method is outweighed by the greater need for skill and the greater time consumed

THE NORMAL CARDIAC SILHOUETTE

For purposes of simplification and standardization we employ three views which usually yield adequate information as to the shape, size and (by fluoroscopy) the pulsations of the heart These views are the posteroanterior the right oblique anterior and the left oblique anterior Occasionally the lateral view is also of value

The Posteroanterior View

About two thirds of the cardiac shadow is to the left, and one third to the right of the mid line (Fig 1) The *right border* is composed of three contours, which from above downward are (1) The *innominate vein* and its continuation into the superior vena cava (2) The *superior vena cava* or, in older individuals, the *ascending aorta* The shadow of the ascending aorta may be seen within that of the superior vena cava even when it does not reach the right border of the heart (3) The *right atrium* which forms a well curved contour separated by a slight indentation from the superior vena cava or aorta and is the largest salient of the right border of the heart Occasionally there may be seen a small portion of the shadow of the inferior vena cava as it enters the lower region of the right atrium

The *left border* also has three main contours which are formed from above downward by (1) The aortic arch continuing into the descending aorta (*aortic knob*) (2) The *pulmonary artery salient* This is composed of the pulmonary artery and its left main branch The left atrial appendage may appear below the pulmonary artery This middle segment is sometimes referred to as the waist of the heart because it is distinctly indented as compared with the bulge of the third contour below it The junction of the pulmonary salient and the latter contour is denoted by a reversal in direction of pulsation the pulmonary salient moving outward while the left ventricular contour moves inward during ventricular systole (3) The *left ventricle* This forms a prominent convex contour, which extends well into the left pulmonic field and curves downward and back toward the mid line to cross the shadow of the left leaf of the diaphragm In the left cardiodiaphragmatic angle there is often a faint triangular shadow

which represents a pad of fat in a fold extending from the pericardium to the mediastinal and diaphragmatic pleura Failure to recognize the cause of this shadow may lead to error in measuring the cardiac size

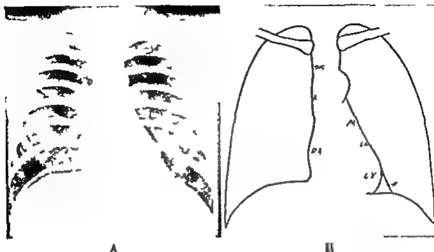

Fig 1 A Normal cardiac silhouette Male aged 45 Posteroanterior view

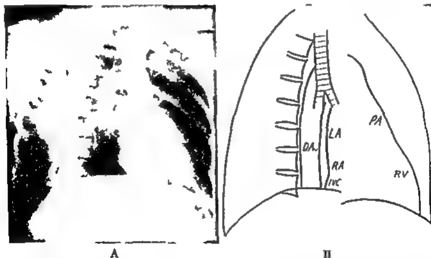

Fig 2 *A* Normal heart Same as in Fig 1 Right anterior oblique view
B Diagram of *A* IVC = inferior vena cava DAo = descending aorta RV = right ventricle LA = left atrium. Other abbreviations as in Fig 1*B*

The Right Anterior Oblique View

The patient facing the screen is rotated anteriorly so that his right shoulder is turned forward toward the screen The angle formed by the shoulders with the screen should be about 30 to 40 degrees for study of the aorta, or 50 to 60 degrees for study of the left atrium The patient s right hand is placed on his head and the dorsum of his left hand is placed on the crest of the ilium, the left elbow being drawn forward at the same time The *anterior border* of the cardiac silhouette in this view (Fig 2) is formed in its upper third by (1) *the ascending aorta and arch* and in its lower two thirds by (2) *the pulmonary artery and* (3) *the right ventricle* With only moderate rotation (30) the left ventricle forms the lower anterior contour

The *retrocardiac space* should be clear at an angle of 30 to 40 degrees and its clarity enhanced by increasing the angle of rotation or by making the patient inspire deeply The posterior aspect of the cardiovascular silhou

developed to obtain three dimensional visualization of cinefluorographic films by the use of two synchronized x ray tubes [17]

The Right Anterior Oblique View

The patient, facing the screen is rotated anteriorly so that his right shoulder is turned forward toward the screen The angle formed by the shoulders with the screen should be about 30 to 40 degrees for study of the aorta or 50 to 60 degrees for study of the left atrium The patient s right hand is placed on his head and the dorsum of his left hand is lower two thirds by (2) *the pulmonary artery and* (3) *the right ventricle* With only moderate rotation (30) the left ventricle forms the lower anterior contour

The *retrocardiac space* should be clear at an angle of 30 to 40 degrees and its clarity enhanced by increasing the angle of rotation or by making the patient inspire deeply The posterior aspect of the cardiovascular silhou

ette from above downward reveals the following structures (1) *The trachea and left main bronchus* form a transparent band, overlying which is the right branch of the pulmonary artery and the superior vena cava (2) *The descending aorta,* which appears as a pale vertical band between the spine posteriorly and the denser posterior cardiac border anteriorly (3) *The left atrium* which is slightly convex and forms the major portion of the posterior cardiac border (4) *The right atrium* with the shadow of the inferior vena cava entering it From posterior to anterior the atrium, and the left ventricle [11, 10] The *anterior aspect* of the cardiovascular silhouette in this position (Fig 3) is composed from above downward as follows (1) *The ascending aorta,* which may be overlapped above by the innominate vein and superior vena cava (2) The *right atrial appendage* which is directed upward and posteriorly, forming an oblique or sometimes almost horizontal segment (3) *The right atrium,* which forms most of the anterior cardiac contour in this view According to angiocardiographic studies the right ventricle may constitute the lowermost

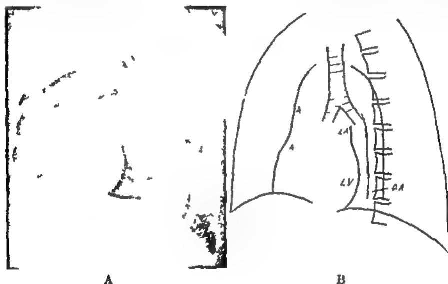

Fig 3 *A* Normal heart. Same as in Figs 1 and 2 Left anterior oblique view *B* Diagram of 3 *A* Abbreviations as in Fig 2*B*

diaphragmatic surface is formed by the inferior vena cava, right atrium and right ventricle

In the right anterior oblique view, the barium filled esophagus is seen between the posterior cardiac border and the descending aorta running an essentially vertical course, but slightly concave anteriorly, with a shallow indentation by the aorta and right bronchus

The Left Anterior Oblique View

The patient is rotated anteriorly so that his left shoulder is toward the screen The angle of rotation is 40 to 50 degrees for study of the aorta, and 50 to 60 degrees for study of the ventricles The patient s left hand is placed on his head, his right hand on his right hip and his right elbow drawn forward This view is especially valuable for the study of the aorta the inflow tract of the right ventricle the left portion of this contour, but most often it is obscured by the right atrium [19] As the body is rotated from the oblique toward the lateral, the right ventricle forms the major portion of the lower contour anteriorly

Along the superior margin the aorta may be followed craniad where it arches over the top of the cardiovascular silhouette and continues into the descending aorta which merges with the shadow of the spine Below the aortic arch is the bifurcation of the trachea forming a transparent region known as the aortic window, traversed by the left pulmonary artery [11] The left main bronchus normally forms an angle of less than 45 degrees with the direction of the trachea

The dorsal aspect is formed in its upper third by (1) *the left atrium,* and in its lower two thirds by (2) *the left ventricle* The cardiac shadow posteriorly should be separated from

the spine if the patient is rotated 45 degrees or more The lower (diaphragmatic) border of the cardiac silhouette is important in this view as it may reveal enlargement of the inflow tract of the right ventricle The anterior two thirds or three quarters of this border represents the diaphragmatic surface of the right ventricle The posterior quarter is formed by the left ventricle Between these two there is often a small indentation which is best seen during deep inspiration and in systole This indentation was said to represent the interventricular sulcus[19] but it does not correspond to the interventricular septum as seen by angiocardiography [19]

As the patient is rotated into a *lateral position* the anterior contours from below upward are the right ventricle and its conus the pulmonary artery and the aorta Posteriorly the left ventricle forms the lower contour and the left atrium the upper

Factors Modifying the Normal Cardiac Silhouette

The appearance of the cardiac silhouette has a considerable range of normal variation depending chiefly on body type (hypersthenic sthenic and asthenic) and on the phase of respiration and the position of the diaphragm but also on age sex height weight and the phase of the cardiac cycle These factors must be considered in evaluating the fluoroscopic findings

In *hypersthenic individuals* with a short, broad rounded chest and elevated diaphragm the cardiac shadow tends to be short wide and situated transversely and the apex appears to be displaced to the left The pulmonary artery segment is relatively short and forms a distinct indentation (waist) with the long prominent left ventricular contour of which the lower portion is often obscured by the diaphragm or fat pad Similar transverse position of the heart simulating left ventricular enlargement may be due to a high diaphragm e g in deep expiration with hepatic enlargement and ascites during pregnancy and in obese subjects with meteorism Scoliosis even the slight scoliosis commonly seen in children produces an apparent enlargement of the cardiac shadow because most of the heart lies to the left of the spine [1] A similar effect is produced by a funnel chest (p 981)

In *asthenic individuals* with a long flat narrow chest, the cardiac silhouette is long and narrow and its major contours only slightly convex In its extreme form this type of heart is pear-shaped, centrally located and is termed the cor pendulum or drop heart The pulmonary artery segment is relatively long and prominent, even in the postero anterior view but more so in the right anterior oblique view, in which it may simulate the appearance seen in right ventricular (pulmonary conus) enlargement A vertical cardiac shadow tends to occur during deep inspiration in the erect as compared with the recumbent position, and in the presence of pulmonary emphysema In infants and very young children the cardiac shadow is centrally located but unlike the drop heart appears globular with equal extent and prominence of its cardiac borders to the right and left of the spine

For Measurement of Cardiac Size etc see p 99

CARDIAC TOMOGRAPHY

Tomography (planigraphy laminography sectional radiography) is a roentgenologic method by which serial layers or planes of the body are examined The desired frontal sagittal or other plane at any body depth is clearly portrayed while other planes, superficial or deep to this plane are blurred out and do not obscure the desired plane Inasmuch as the individual cardiac chambers and the great vessels are located predominantly in different planes tomography of the chest can be utilized to examine individual structures of the heart and vascular pedicle without obscuration by overlying or subjacent cardiac chambers or other structures [21 6]

Tomography is accomplished by having the focal point of the roentgen ray tube move in one direction while the film on the other end of the same axis moves simultaneously in the opposite direction [1] The center of this axis which may be raised or lowered is at the level of the body plane to be examined That plane remains constant with respect to the axis of the x rays and its projection on the film and is clearly depicted, while the other planes photographed successively by the moving tube are blurred out because they are in motion and appear on different portions of the film The chief disadvantage is that multiple sections must be studied involving considerably more time and expense than conventional radiography

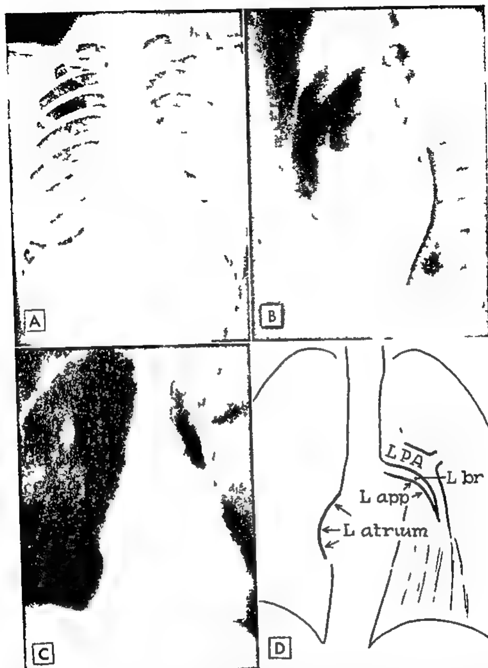

Fig 4 4 Conventional posteroanterior roentgenogram of the chest of a 32 year old woman with mitral teno is Left lower contour displaced to left Prominent pulmonary arteries Prominent left atrial appendage (left middle contour)

B Left lateral view of same showing left atrium indenting barium filled e ophagus

C Tomogram (posterior section) of same Enlarged left atrium protruding on to right border Left atrial appendage elevating left stem bronchus and left pulmonary artery Ab ence of prominent left lower contour because apex is formed by enlarged right ventricle which is seen in anterior sections Left ventricle seen in this posterior section is not prominent or enlarged

D Tracing of C

It has been claimed that cardiac tomography may aid in the differential diagnosis between mitral stenosis and mitral insufficiency, and between aortic or pulmonic insufficiency combined with mitral stenosis, by distingui hing left from right ventricular enlargement Hypertrophy and dilatation of the right ventricle is disclosed by enlargement

of the right ventricular shadow in anterior planes with disappearance of this enlarged shadow in posterior sections Left ventricular hypertrophy is indicated by the presence of an enlarged ventricular shadow in posterior planes

Left atrial enlargement has been shown clearly by tomography (Fig 1)[14] Patent ductus arteriosus has been revealed as a distinct vascular shadow in a median plane of a lateral projection of the thorax Tomography is said to outline clearly coarctation of the aorta in a suitable plane of the left anterior oblique projection Calcification of the mitral or aortic valve is more clearly depicted by cardiac tomography than by conventional roentgen ray films or fluoroscopy Aneurysms of the aorta or pulmonary artery may also be clearly disclosed

The cardiac volume has been determined by axial tomography i e by films of about a *dozen parallel cardiac planes perpendicular to* the long axis of the subject and a known fixed distance apart[4, 8] The cardiac areas in the various sections are measured and the volumes calculated by multiplying by the distances between sections

ROENTGENKYMOGRAPHY AND ELECTROKYMOGRAPHY

Roentgenkymography

This is the technique of recording the pulsations of the cardiac borders by means of roentgen rays The latter are directed at moving film which comes in contact with a stationary grid with vertical and horizontal slits The borders of the cardiac silhouette do not appear as smooth outlines, but have a horizontal picket fence conformation representing the successive positions of the border in diastole (outward) and systole (inward) Roentgenkymography has been employed infrequently as a possible aid in the differentiation of pericardial effusion from cardiac enlargement and in the study of myocardial infarction and ventricular aneurysm It is of little if any clinical importance at the present time[■]

Electrokymography

This is a method which employs a photoelectric device for the graphic representation of the movements of the cardiac borders as they appear on the fluoroscopic screen[28, 29, 31] A multiplier type of photosensitive tube containing *a rectangular slit covered by a small* fluorescent screen directly over the sensitive surface of the tube is attached to the patient's side of the conventional fluoroscopic screen perpendicular to the cardiac border which is being studied As the heart is projected on the fluorescent screen outward (lateral) movement of the cardiac border partially obstructs the slit and reduces the beam of x rays This in turn reduces the amount of fluorescent light affecting the photosensitive tube and the strength of electric current emitted Conversely an inward (medial) movement of the cardiac border increases the intensity of the beam of x rays and of fluorescent light and thereby the amount of electrons generated by the phototube

When the photosensitive tube is so placed as to be affected by x rays passing through the cardiac structures rather than through its borders, changes in cardiac density result in corresponding changes in the intensity of the *x ray beam and in the current generated by* the photosensitive tube which are inversely proportional to the posteroanterior thickness of the organ (densimetry) The resulting current of varying intensity is suitably amplified and recorded as a phasic curve by an electrocardiograph The polarity is arranged so that an outward (lateral) movement of a cardiac border or an increase in density of a cardiac chamber produces an upward deflection in the electrokymographic curve (EKY) while an inward (medial) movement of a cardiac border or a diminution in cardiac density causes a downward deflection

For purposes of timing and as a reference frame for the events of the cardiac cycle the EKY is taken simultaneously with tracings of the carotid pulse[6] and heart sounds[9] or electrocardiogram[■] or with simultaneous electrocardiogram and pressure pulses of the right ventricle and pulmonary artery (by cardiac catheterization)[24] There is a time lag of 0 015 to 0 025 sec in recording by the EKY The subject standing behind the fluoroscope screen, may be placed in any desired position e g the posteroanterior, right anterior oblique and so on Studies are usually made of the ventricles,[■] the atria[5] the aorta and pulmonary artery[6] and *if desired* of the peripheral pulmonary arteries It may also be used to study the pulsation of suspected aneurysms

A normal electrokymogram is depicted in *Figure 5*

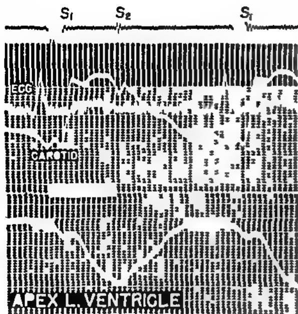

Fig 5 Normal ventricular electrokymogram from border of apex of left ventricle Downward limb and trough during systole opposite in direction to upward limb and crest of simultaneous carotid pulse

Evaluation of Electrokymography

Electrokymography is of very limited practical value in clinical cardiology At present it is employed essentially in research *It has been utilized chiefly in an attempt to* shed more light on the mechanical changes of the heart in the various phases of the cardiac cycle, including isometric contraction and relaxation Physiologic studies have also been *made of the effect of drugs on the mechanical* behavior of the heart

More or less characteristic patterns have been noted in a variety of clinical conditions, but almost always these abnormalities can be detected more simply and with greater certainty by other means Electrokymography is most likely to be useful in those cardiac diseases which *result* in *localized* cardiac damage or gross impairment of cardiac filling and contraction

A characteristic electrokymographic pattern has been found in constrictive pericarditis (Fig 6) The electrokymogram may disclose distinctly abnormal asynchronism in ventricular contraction in cases of bundle branch block [27] A reversal of the normal ventricular EKY pattern may be demonstrated at the border of infarcted myocardium (Fig 7) or the site of a ventricular aneurysm [8] In congenital heart disease high amplitude in pulmonary *artery electrokymograms* may be disclosed in cases of high pulmonary artery pressure, e g

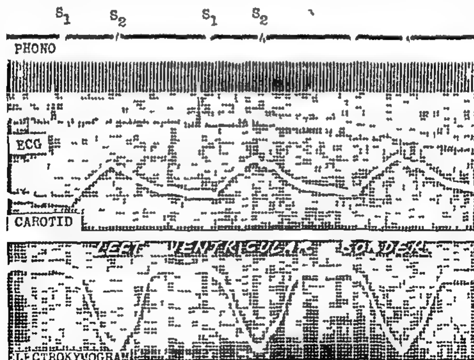

Fig 6 *Electrokymogram left ventricular border in constrictive pericarditis Alternate V and flat-top curve* Flat-top (plateau) represents impaired diastolic filling in first part of horizontal segment isometric contraction in latter portion Down stroke of V represents ejection upstroke isometric relaxation and early diastole

interatrial septal defect and low amplitude in cases of pulmonary stenosis, especially over the peripheral lung fields. A sharp anacrotic notch in the aortic electrokymogram is observed in cases of subaortic and aortic stenosis. More or less distinctive findings in mitral and tricuspid valvular disease have been recorded.

There are a number of limitations to the value of electrokymography imposed by the method itself. There is considerable variation in normal patterns, the range of which has not been satisfactorily defined. The observed pattern may differ with change in the site of application of the electrokymograph slit on a given chamber segment. The effect of alteration of cardiac volume during the cardiac cycle is modified by superimposed positional changes. Considerable difficulty arises in attempts to correlate various portions of the EKY curves with the different phases of cardiac cycle, for even with the use of simultaneous carotid pulse tracings, phonocardiograms and electrocardiograms there is disagreement in points of reference for the beginning and end of the different cardiac phases.[31]

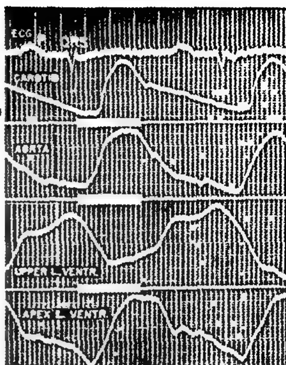

Fig. 7. Electrokymogram in myocardial infarction. Reversal of pulsation at apex of left ventricle. Paradoxical (outward) pulsation of apex shown by upstroke and crest during systole in opposite direction to upper border of left ventricle and same direction in simultaneous carotid pulse. Compare Fig. 5.

ANGIOCARDIOGRAPHY

Angiocardiography is the roentgen ray method of portraying the cardiac chambers and great vessels and the course of the blood flow in these structures by opacification with an intravenously injected radiopaque solution.[34, 39, 40]

Radiopaque Contrast Substances

The contrast substances usually employed are *Diodrast* (iodopyracet) in 70 per cent solution, *Neo-iopax* (uroselectan B sodium iodomethamate) in 75 per cent solution and more recently *Urokon* (sodium acetrizoate) in 70 per cent solution.[39] These solutions contain between 44 and 52 per cent of iodine. The *dose* is usually 1 cc. of the contrast solution per kg. body weight in infants and young children with a maximum of 15 cc. Adults are given 40 to 50 cc. and children intermediate doses between 15 and 40 cc. according to their size.

Technique of Angiocardiography[40, 47]

The patient should be hospitalized, although adults may have the procedure as outpatients. Breakfast is omitted if the examination is performed in the morning and lunch is omitted if it is made in the afternoon. The patient is premedicated with a barbiturate one hour before the procedure. As a rule opiates are omitted, especially in cyanotic infants, but occasionally morphine sulfate (0.2 mg. per 10 lbs. of body weight) is desirable for angiocardiography in the infant. Codeine or Hycodan in small doses may be administered if necessary to inhibit a cough which may interfere with obtaining satisfactory films. Penicillin may be given prophylactically. General anesthesia is administered to infants, young children and all others who cannot otherwise cooperate.

The *injection of the contrast material* is performed in a room equipped for roentgen ray examination. Control films are first made in the same projections as will be used for angiocardiography. These are developed and inspected before injection of the contrast material.

A suitable antecubital vein, or occasionally a cephalic vein at the wrist, is chosen for injection in adults and the saphenous or external jugular vein in young children. Under sterile precautions a cut-down is made over the vein through a procaine wheal and

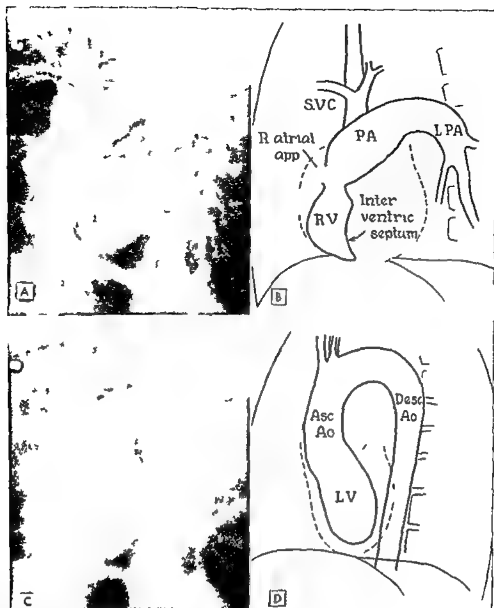

Fig 8 1 Angiocardiogram of right heart and pulmonary arteries Left anterior oblique view two seconds after injection
B Tracing of *A*
C Angiocardiogram of left heart and aorta Left anterior oblique view seven seconds after injection
D Tracing of *C*

special needle with a stopcock unit or plastic tube is inserted into the vein and kept in place with adhesive The patient is positioned as desired usually in the left anterior oblique or posteroanterior position After it is determined that there is a free flow into the vein the syringe containing the radiopaque contrast solution is attached to the needle The injection is made rapidly as the patient starts a deep inspiration and is completed in two seconds The first roentgen ray exposure is made while the patient holds his breath in full inspiration Rapid serial angiocardiographic films are then made with the aid of the Fairchild automatic roll film magazine, which yields films at the rate of about two exposures per second

Side Actions and Dangers of Angiocardiography

Angiocardiography is usually an unpleasant

experience for the patient Following Diodrast, there is a bitter or metallic taste in the mouth, after which a sense of heat pervades the entire body but usually subsides within five or ten minutes Weakness is common Dizziness nausea, vomiting urticaria and occasionally syncope or shock may occur There may be a transient febrile reaction several hours after the injection Thrombosis of the injected vein occurs very frequently Deaths have occurred in more than 20 acknowledged cases

After Neo-iopax there is an initial sense of heat followed by a throbbing headache which may be inten e Weakness and thirst are common complaints Flushing or pallor is often noted Nausea thrombosis of the injected vein and syncope may occur as commonly as after Diodrast Cough after 5 to 8 seconds while the pulmonary capillaries are filling is not uncommon and may interfere with exposures during filling of the left ventricle Death after Neo-iopax is probably rare The reactions after Urokon appear to be milder as well as less unpleasant to the patient than after Diodrast or Neo-iopax

Tachycardia is usual after the injection The blood pressure may fall at first but then there is a marked rise in systolic and pulse pressure The hypotensive reaction is most prominent after Diodrast Electrocardiograms may disclose premature ventricular contractions and other arrhythmias[19] prolongation of the Q T interval and diphasic or inverted T waves The ballistocardiogram may be quite abnormal

Goodwin et al[44] reported 2 deaths among 118 cases but neither was directly attributable to the angiocardiography Dotter and Jackson[19] reported a case fatality rate of 0 4 per cent in 6739 cases of all types

Structures Depicted in Successive Angiocardiograms

Examination of the successive angiocardiographic films taken at definite recorded intervals after injection reveals not only the size, position and configuration of the various vessels and cardiac chambers but especially the sequence and time of filling of these structures[5, 18] At one second the right atrium and its appendage are filled and by two seconds the right ventricle and usually also the pulmonary arteries (Figs *8A*, *9A*) At three seconds the right atrium is fading and by four seconds is empty, whereas the right ventricle may be seen in diastole By six to eight seconds after injection, the contrast material normally has left the right side of the heart and opacifies the left atrium The left atrial appendage is usually not well visualized, but the pulmonary veins may be observed entering the left atrium By seven to nine seconds the left ventricle and aorta are also opacified (Figs *8C*, *9C*) The interventricular septum is seen to be convex to the right The thoracic aorta and the arteries arising from the arch are best studied in the left anterior oblique view

Indications for and Value of Angiocardiography

Angiocardiography is most commonly indicated in cardiologic practice (1) in certain cases of congenital heart disease (2) in distinguishing aneurysms of the great vessels from pulmonary or mediastinal tumors (3) in the diagnosis of suspected pulmonary arteriovenous fistula (4) in determining the nature of cardiac or paracardiac shadows e g ventricular aneurysm or aneurysm of the sinus of Valsalva versus intrinsic pulmonary lesions (5) in differentiating pericardial effusion from cardiac enlargement

Angiocardiography may be desirable for the surgeon not only in providing or confirming the diagnosis of a congenital cardiac lesion, but also in disclosing or excluding associated anomalies and in revealing the size position and configuration of structures which may be important in the surgical procedure[43] However since angiocardiography is a relatively formidable unpleasant and occasionally dangerous procedure, its performance should be clearly justified by the value of the information which it is expected to provide It should be performed only after simpler conventional methods of study, including cardiac catheterization if necessary, have failed to provide an adequate basis for undertaking or rejecting a surgical procedure or if the surgeon requires a more exact delineation of the cardiac or vascular abnormalities Angiocardiography may clearly depict some but not all of the anomalies of a given congenital cardiac syndrome, and occasionally its findings are misleading unless they are carefully correlated with clinical roentgenologic electrocardiographic and catheterization studies

Angiocardiography is most likely to be employed in young cyanotic infants in whom an exact diagnosis is uncertain after conventional

clinical and laboratory examinations, and in whom cardiac catheterization is not diagnostic or cannot be performed But angiocardiography is al o most dangerous in this group It may not be essential for the diagnosis of tetralogy of Fallot, but it may help the surgeon in demonstrating the position and number of the great vessels and other anatomic features It differentiates Fallot s tetralogy from pulmonary stenosis with right-to-left shunt through the atrial septum Angiocardiography is es ential for the diagnosis of complete transposition of the great vessels or the Bing Taussig heart It also discloses the presence or absence of a pulmonary artery in cases of pulmonary atresia and the source and nature of blood supply to the lungs Similarly angiocardiography not only confirms a clinical diagnosis of tricuspid atresia but indicates that there is under vascularization of the lungs and reveals whether there is a pulmonary artery which can be used for a Blalock operation Angiocardiography is diagnostic in cases of Ebstein s anomaly of the tricuspid valve and in truncus arterio us Although angiocardiog

raphy is usually diagnostic in cyanotic types of congenital heart disease with right to-left shunt it usually does not distinguish between a tetralogy of Fallot and the Ei enmenger complex nor is it diagnostic of patent ductus arteriosus with pulmonary hyper tension and reversal of shunt Cardiac catheterization is necessary in most of these cases Angiocardiography usually provides a preci e diagnosis of anomalous entrance of the pulmonary veins into the superior or inferior vena cava or right atrium

Angiocardiography is infrequently indicated in noncyanotic cases of congenital heart disease but it may be desirable in cases of coarctation of the aorta to delineate the na ture and extent of the constriction and the position of related vessels *Thoracic aortog raphy* provides an even more accurate pic ture Angiocardiography is rarely necessary and is less useful than cardiac catheterization in cases of interatrial or interventricular septal defect, pulmonary stenosis or patent ductus arteriosus but it may occasionally be desirable to determine the presence and na ture of associated defects Angiocardiography clearly depicts the presence and type of dextrocardia and the presence of dilatation of the pulmonary artery

Rapid Biplane Angiocardiography

This is a method of synchronous angio cardiography in two planes perpendicular to each other with a speed of 10 to 12 exposures per second[4] [illegible] It permits the study of the atria and ventricles in both systole and diastole Frontal and lateral exposures, or left and right oblique exposures are synchronized by a motorized table An electrocardiogram made during the procedure fixes the precise time between ex posures and registers the cardiac phase Because of the numerous exposures appro priate precautions must be taken to avoid radiation hazards Flash exposures should be used instead of uninterrupted irradiations Dotter[38] called attention to the value of short-duration roentgen exposures for angio cardiography to improve diagnostic accuracy and to avoid the expense of the multiple exposures and films required in rapid bi plane angiocardiography By the use of an electronically controlled grid operated electron tub in series with the diagnostic tube three millisecond clinical radiographic ex posures could be made

By the technique of rapid biplane angiocardiography it is possible to demonstrate more discretely than by conventional angiocardiography the normal and pathologic anatomy of the cardiac chambers and great vessels and to reveal information as to normal and abnormal cardiac dynamics [illegible] When placed side by side the films of two cardiac planes permit a three-dimensional apprecia tion of the capacity as well as configuration of the cardiac chambers The volume of indi vidual chambers can be estimated by simul taneous measurements of the cardiac sil houettes in the two perpendicular projections and the stroke volume by the difference of the calculated volumes in systole and diastole

Photofluorography (cineangiocardiogra phy) *may be used instead of direct roent* genography to obtain serial angiocardiograms[46] But although this may provide an increased rate of exposures the cin ma tographic projections lack the details and sharpness of direct angiocardiograms Fur thermore there is a much greater irradiation exposure of the patient with photofluorogra phy

Selective Angiocardiography

Selective angiocardiography is designed to improve the contrast visualization of various portions of the heart or great vessels by con centrating the contrast medium in the area to be studied[47] [illegible] The contrast medium, e g , 70 per cent Urokon (1 to 1 [illegible] ml /kg body weight), is injected through a catheter with the aid of a pressure apparatus Radiographs are taken in at least two planes at right angles to each other

In order to effect the visualization of the entire intrathoracic circulation the catheter tip is placed in the most proximal part of the subclavian or innominate vein The opening in the catheter is 5 cm from the tip To visualize the right atrium the tip of the catheter is placed in the lower part of the superior vena cava To visualize the right ventricle the catheter tip is situated in the pulmonary conus where it should be made to lie steady Stenosis of the infundibulum and of the pulmonary valves is thus distinctly visualized (Fig 10) In cases of suspected tetralogy of Fallot the catheter is placed in the aortic orifice and the contrast medium will visualize the aorta innominate carotid and subclavian arteries In addition since the catheter slips down into the right ventricle

Fig 10 Selective angiocardiography Pulmonic stenosis Man aged 45 *A* Systole Note dome-shaped stenotic pulmonic valve (white arrow) Jet (J) of contrast material forced through central orifice of stenotic pulmonic valve from infundibulum (I) into pulmonary artery (PA) CSV crista supraventricularis

B After pulmonary valvulotomy Broad jet of contrast medium now spurts through dilated opening Infundibulum is widened (From Kjellberg et al Diagnosis of Congenital Heart Disease Yearbook Publishers Inc)

during the injection the right ventricle pulmonary conus and pulmonary artery are visualized

Fluoroscopic Image Amplification

This apparatus represents a major advance in diagnostic roentgenology and overcomes many of the deficiencies of cardiac catheterization and angiocardiography It particularly enhances the value of combined cardiac catheterization and selective angiocardiography

The image amplifier increases the brightness of the fluoroscopic image more than 1000 times (Philips) and permits visualization of mediastinal structures in a lighted room Two observers may study the amplified image simultaneously through attached optical periscopes The amplified image can be photographed or scanned by a television camera and reproduced on a television screen, or photographed at 18 to 64 frames per second with a 35 mm motion picture camera and then projected in slow motion for study At present commercial equipment is limited to a field diameter of about 12 cm but this is adequate for detailed study of specific congenital cardiac lesions in young children or infants

The image amplifier employed with combined cardiac catheterization and selective angiocardiography, is capable of demonstrating the pulmonary venous return the left heart and aorta the coronary circulation pulmonic valvular and infundibular stenosis *patent foramen ovale ventricular septal* defect truncus arteriosus the presence and degree of dextroposition of the aorta, and anomalies of the aortic arch

Thoracic Aortography Retrograde Aortography

The contrast medium is injected retrograde through the carotid artery or through a catheter introduced through the radial or ulnar artery into the aorta [31-45] The tip of the catheter must be in the middle of the ascending aorta—not lower because of danger to a coronary artery not higher because of danger to the innominate Thoracic aortography has been used mostly in cases of suspected coarctation of the aorta and clinically atypical patent ductus arteriosus but also in suspected aortic hypoplasia aorticopulmonary fistula and truncus arteriosus The

radial or ulnar artery must be sacrificed The procedure is associated with some hazard Thoracic aortography may also be performed by percutaneous insertion of a polyethylene catheter through the brachial artery

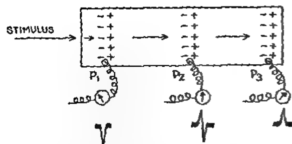

Fig 12 Depolarization of single muscle fiber Impulse starting at S proceeds from left to right P_1 P_2 P_3 are points in surrounding volume conductor and below them are curves registered by galvanometer at those points

muscle fiber is depolarized As depolarization proceeds, the activity front moves from active toward resting muscle and a positive charge (source) precedes while a negative charge follows the path of the impulse or the activity front If an electrode is placed in a conducting medium surrounding the muscle fiber at point P_1 and connected with one pole of a galvanometer while the other pole of the galvanometer is connected to some distant or zero point the galvanometer will register a negative electromotive force since the activity front is moving away from the electrode at P_1 and the electrode at P_1 is therefor facing the negative charge By convention the galvanometer recording device is so arranged that a positive voltage is recorded as an upward deflection and a negative as a downward deflection Hence a negative wave is recorded from the electrode at P_1 On the other hand an electrode in the conducting medium at P_2 would first record a positive deflection as the wave of depolarization approached it and then a negative deflection as the depolarization front passed it An electrode at point P_3 would record only a positive deflection since the wave of depolarization is continually approaching it

With reference to P_2 the instant at which the muscle underlying the electrode is completely depolarized is recorded by the intrinsic deflection [44] The *intrinsic deflection* is a rapid downward deflection from the peak of maximum positivity The greatest positive potential is recorded just as the activation front is about to reach the electrode There is then a sudden fall of potential to zero when the center of the activation front is at the electrode and a rapid increase in negative potential as the activation front passes just distal to the electrode If the electrode is at the last point to be depolarized the downward deflection reaches zero, i e the iso electric line, but does not become negative When the electrode is not directly on the surface of the muscle fiber but somewhat removed in the conducting medium, as for example when electrodes are placed on the body surface rather than on the contracting myocardium, there is a similar but somewhat slower fall from maximal positive to zero or to maximal negative potential, and a somewhat less steep downward deflection is recorded since the activation front is some distance beneath the recording electrode This deflection is termed 'intrinsicoid deflection '[44] However, there is evidence[45] that the *intrinsicoid deflection* in a given area of the heart may not occur at the instant of the sharp downward deflection but somewhat later along the downstroke or even at its nadir This may be related to the vector concept that potential differences on the body s surface are not determined exclusively or even largely by localized potentials (proximity potentials) in the subjacent myocardium i e just below the electrode on the heart s surface, but by the relation of the electrode to the resultant vector of all the electromotive forces generated by the heart

Repolarization

After depolarization has occurred, certain physicochemical processes restore the membrane doublets and the depolarized membrane, cell or fiber is again polarized, with positive charges on the outer and negative charges on the inner side of the surface (Fig 11, *F-I*) During repolarization positive charges face the repolarized areas while negative charges face the areas still depolarized Thus the front of repolarization proceeds with negative charges in advance and positive charges behind

If the depolarized fiber were entirely uniform in its composition and physicochemical properties repolarization would begin first in that region where depolarization had begun and would follow the same path as that of activation If the impulse of depolarization in such a uniform fiber were proceeding toward a point in a surrounding volume conductor where an electrode was connected to a galvanometer a positive wave of depolarization would be recorded since the electrode would be facing the positive charges of the activation front throughout

depolarization If repolarization followed the same course, a negative wave would now be recorded at the same point since the electrode would be continuously facing the negative charges of the repolarization front This alternation of a positive and negative wave is termed a diphasic action current

Repolarization occurs relatively slowly compared with the rapid development of depolarization and the peak potential difference is not as great However the total quantity of electromotive force generated during re-*polarization* (average voltage multiplied by time) is equal to that generated during depolarization The wave of depolarization in a contracting *uniform fiber* is therefore of opposite polarity longer duration and lower voltage than that of the wave of depolarization But the area between the baseline (isoelectric line) and the wave of repolarization is equal to the area of the wave of depolarization

If the muscle fiber is not uniform repolarization may not begin first in the area which was first depolarized and the course of repolarization may not follow the same course as that of depolarization Thus if physicochemical changes occur more rapidly at the right than at the left end of a muscle fiber (e g as a result of cooling the left end) depolarization develops more slowly and persists longer at the left end Accordingly repolarization begins first at the right end where depolarization is first *completed If this muscle fiber is stimulated* at the left end the process of depolarization proceeds from left to right but the front of repolarization begins at the right end (while activation is still present at the left) and proceeds toward the left (Fig 13)

Thus an electrode at the right end of the fiber would be facing positive charges throughout repolarization as well as throughout depolarization The galvanometer records a positive wave during depolarization followed by another positive wave during repolarization This corresponds to the situation in the normal human heart, in which differences in the duration of depolarization in different areas of the ventricles result usually in positive waves representing ventricular repolarization as well as ventricular depolarization The differences in intensity and duration *of activation of different areas of* cardiac muscle are discussed later under the heading 'ventricular gradient' (p 51)

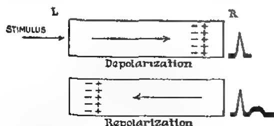

Fig 13 Fiber with slower metabolism and more prolonged depolarization at left end (L) is stimulated at left end Galvanometer at right (R) records a positive wave during depolarization Repolarization begins at right proceeds to left and produces another positive wave

THE LEADS OF THE ELECTROCARDIOGRAM

Cardiac activity is associated with depolarization and repolarization of cardiac muscle and the development of an electrical field in the surrounding tissues The tissues surrounding the heart are considered as a relatively uniform volume conductor for purposes of presenting clinical electrocardiography Electrodes placed on the surface of the trunk or extremities are situated within the electrical field of the heart When these electrodes are connected with the galvanometer in the electrocardiograph machine changes in electrical potential from moment to moment at the sites of these electrodes are recorded as a continuous curve the electrocardiogram, with time as the abscissa and *voltage as the ordinate*

An electrocardiographic *lead* or *derivation* refers to a pair of electrodes on the body s surface between which there is a potential difference and from which the current is led to the electrocardiograph The term ' lead ' is applied also to the electrocardiogram thus obtained from a given pair of electrodes When both electrodes are at approximately equal distances from the heart the lead is called a bipolar lead A so called ' unipolar lead denotes that one of the two electrodes is relatively distant from the heart In clinical practice 12 leads are usually recorded routinely the three standard (bipolar) limb leads, three unipolar limb leads and six unipolar precordial leads Selectors on the electrocardiograph, chosen by means of a switch adjust the proper lead arrangements after all the electrodes are properly placed on the extremities and the precordium and suitably connected to the electrocardiograph

The Standard Leads

The standard limb leads are bipolar leads. Lead I is taken between electrodes placed on the right and left forearms (conventionally referred to as arm); lead II is between the right arm and left leg; lead III is between the left arm and left leg. The polarity of the electrocardiograph's galvanometer is so arranged that an upright wave is recorded in lead I when the left arm electrode is positive relative to the right arm electrode; an upright wave appears in lead II when the left leg electrode is positive relative to that on the right arm; an upright wave occurs in lead III when the left leg electrode is positive relative to that of the left arm.

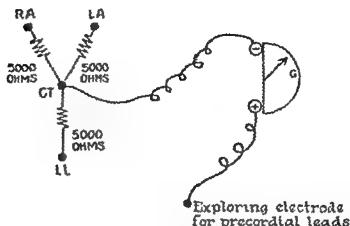
The Einthoven Triangle and The Einthoven Law (Equation)

Einthoven conceived of the human torso as a sphere at the center of which was an electric current dipole representing the heart's electrical activity. The right shoulder, left shoulder and left hip were regarded as forming an equilateral triangle (the Einthoven triangle) whose apices are on the surface of the sphere; the plane of the triangle was assumed to be parallel to the frontal plane and to contain the dipole at its center. The limb lead electrodes are regarded as being situated at the apices of the triangle, but for practical reasons they are actually placed on the right and left forearms and left leg, which are linear extensions of the shoulders and left hip.

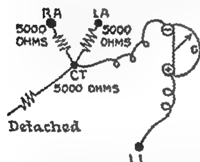
The *Einthoven triangle hypothesis*[1] also assumes that the tissues surrounding the heart form a uniform volume conductor and therefore conduct the electrical impulse uniformly *to the body surface, and further* that the sites of the limb electrodes, represented by the apices of the Einthoven triangle, are relatively distant from the heart and each other and that the heart may be represented as a point source of electromotive forces denoted by the center of the equilateral triangle.

None of these assumptions is exactly correct since the heart is somewhat eccentrically placed in the torso[illegible, 25]; the triangle formed is not equilateral; the heart is not equidistant from the apices, the tissues are not uniform with respect to their conductivity[7] and the size of the heart is relatively large compared to the distance of the electrodes from the heart. However, the assumptions approximate the facts sufficiently to have made the Einthoven hypothesis extremely useful in our understanding of the findings in the electrocardiogram of the human heart.[illegible] The Einthoven hypothesis is the basis also for the concept of the mean electrical axis and the determination of the manifest electromotive forces of the heart, which are discussed later under vectorcardiography (p. 3?).

Since the standard leads are bipolar leads they reveal differences of potential at two sites but do not actually disclose the potential at any single extremity. The lead potential difference in microvolts at any instant is as follows:



Lead I = Left Arm minus Right Arm
Lead II = Left Leg minus Right Arm
Lead III = Left Leg minus Left Arm



It is apparent from these equations that if electrocardiograms were taken simultaneously with the three leads at any given instant the potential in lead II is equal to the sum of the potentials of leads I and III (Einthoven's Law or Equation).[2] When the leads are recorded in succession as they are usually, this relationship is only approximately correct, but may be used as a check on the accuracy of the application of the electrodes.

Unipolar Leads and Wilson's Central Terminal

Unipolar leads are designed to disclose the potential at a given site relative to some distant or zero point in the electrical field of the heart. One electrode placed relatively close to the heart is termed the exploring electrode, while the other placed at a relatively distant site is termed the indifferent electrode. Even so-called unipolar leads are *actually bipolar in that two wires running to* different electrodes are required to complete the electrical circuit to the galvanometer. However, while one wire leads to the exploring electrode on an extremity or chest wall, the other wire leads to an indifferent electrode with negligible potential. But no matter how distant from the heart is the location of the indifferent electrode on the body surface, its potential is not negligible, hence various methods have been suggested to obtain such an electrode with zero or negligible potential.

The method of Wilson employs a *central terminal* representing an approximate "zero potential."[illegible] The central terminal is connected on the one side with the negative pole of the electrocardiograph galvanometer and on the other with each of the three extremi

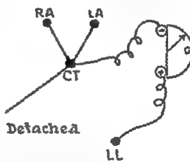


Fig 14 Connections for Wilson's Central Terminal for precordial leads Wilson's Central Terminal for unipolar limb leads and Goldberger's Central Terminal for unipolar limb leads CT central terminal G galvanometer RA right arm LA left arm LL left leg (foot)

ties the right and left arms and the left leg with a resistance of 5000 ohms interposed between each of these extremities and the central terminal (Fig 14) The positive pole of the electrocardiograph galvanometer is connected by another wire to the exploring electrode and a positive potential at the exploring electrode is recorded as an upright wave

The potential at the central terminal is the average of the potentials at these extremities If the assumptions on which the Einthoven triangle hypothesis is based are valid the potential at the central terminal is virtually zero since the sum of the potentials at the three apices representing the site of the limb electrodes at a given instant is equal to zero (Einthoven equation) Furthermore the central terminal potential does not fluctuate from moment to moment during electrical activation and repolarization of the heart if the approximate validity of the Einthoven hypothesis is accepted Actual measurements by experimental methods are in essential support of these concepts[18] although they have been variously criticized[3, 57, 58, 10] The accuracy of the assumption that the central terminal is at zero potential depends not only on the validity of the Einthoven equilateral triangle hypothesis but also on the identical values of the skin resistance under the three extremity electrodes Differences in skin resistance are difficult to avoid in practice but may be minimized by carefully scrubbing the patient's skin before applying the electrodes and by the introduction of the fixed resistors Various experimental studies including the use of torso models filled with a

homogeneous conductor in which is immersed a current dipole eccentrically placed, indicate that the Wilson central terminal voltage departs from the ideal zero value by approximately 15 to 40 per cent of the maximum value of the manifest heart vector [21]

Unipolar Precordial or Chest Leads

To obtain unipolar leads from the chest wall, the exploring electrode connected with the positive pole of the electrocardiograph galvanometer is placed successively on various sites of the precordium while the negative pole is connected to the Wilson central terminal (p 22) Unipolar leads from either the chest or limbs are labeled V leads followed by a symbol denoting the site of the electrode The usual unipolar precordial leads are taken from the following sites [2]

- V_1—Fourth intercostal space immediately to the right of the sternum
- V_2—Fourth intercostal space immediately to the left of sternum
- V_3—Midway between V_2 and V_4
- V_4—Fifth intercostal space in midclavicular line
- V_5—Left anterior axillary line at same horizontal level as V_4
- V_6—Left mid axillary line at same horizontal level as V_5

Additional leads are occasionally desirable V_{3R} and V_{4R} are taken with the electrode at positions corresponding to V_3 and V_4, respectively but on the right side of the sternum V_{4R} being particularly useful to reveal right ventricular hypertrophy and conduction disturbances of the heart, the latter especially in children V_7 may be taken at the same horizontal level as V_6 but in the posterior axillary line while V_8 (or V_B) is at the same level in the left scapular line A unipolar chest lead from the xiphoid or ensiform process is designated V_E Leads may also be taken at higher levels e g, in the line of V_4 but in the fourth third or second intercostal space These are designated $V_{4(4)}$, $V_{4(3)}$ or $V_{4(2)}$, respectively or the symbols V'_4, V''_4, or V'''_4 respectively may be used There are also advocates of the use of chest foot leads (CF leads) in which the negative pole is connected with the left leg electrode and the positive pole to the various chest sites (CF_1 CF_2 CF_3 etc) Similarly, chest right arm leads (CR leads) or chest left arm leads (CL leads) may be taken with the negat pole connected to the right or left arm spectively or chest-back leads (CB_1 etc) with the negative pole connected back Special bipolar thoracic leads h employed to explore the cardiac elect in the horizontal plane [15]

Unipolar Limb Leads

The exploring electrode is pl limb under study and is con positive pole of the electrocard the wire from the other pole a central terminal (Fig 14) C fied the central terminal respects He removed the ances since he felt that th influence others have ind introduce additional err the wire from the centr under study since th to the negative ele therefore counter wire which lead po itive pole (I resulting elect per cent great that limb terminal [41] He are call d designated follow mented) follow cerned i e aVR for the left arm, and aVF for the foot) The a' is omitted if the Wilson central terminal is used and the leads are not augmented Actually Wilson employed an augmented limb lead in that he disconnected the central terminal connection to the limb under study, but retained the 5000 ohm resistances (Fig 14) The central terminal is no longer at zero potential when one of the extremity wires is detached as in the augmented leads The original central terminal of Wilson with virtual zero potential is still retained for precordial unipolar leads In actual practice electrodes are attached to the four limbs and to the various precordial sites, while the proper leads are obtained by merely turning the switch in a lead selector which is incorporated in the electrocardiograph

Esophageal Leads[26, 6, 33]

An esophageal electrode which is a small German silver pellet is attached to a plastic tube or duodenal catheter, and is connected

by insulated copper wire to the left arm lead and thence to the positive electrocardiograph pole. The other pole of the electrocardiograph attached to the right arm lead is connected with the central terminal of Wilson and the electrocardiograph is set at lead I. The tube or catheter is passed into the stomach and electrocardiograms are recorded from successive esophageal levels as the tube is withdrawn gradually from the subdiaphragmatic to the supracardiac level. The site of the electrode is determined from measurements marked on the tube and by the presence of an intrinsic deflection of the P wave as long as the tube is contiguous to the atrium. Esophageal electrocardiograms record atrial, transitional or ventricular deflections according to the position of the electrode. The first group is recorded when the electrode is 32.5 to 47.5 cm. from the anterior nares, the second between 40 and 50 cm. from the nares, and the third from 42.5 to 52.5 cm. or more from the nares. Because of the inaccuracies in estimating the electrode's position by the distance from the nares, Scherlis et al.[8] determined its position by fluoroscopic control. They employed a rubber tube with fifteen electrode rings of German silver 1.75 cm. apart, each with its thin wire connection for electrocardiographic attachment. Esophageal leads are designated by the symbol E followed by a numerical subscript denoting the distance in centimeters from the mouth or external nares to the esophageal electrode, e.g., E_{46}. Esophageal leads may be useful in the diagnosis of atrial enlargement, arrhythmias and infarction of the posterior wall of the left ventricle.

Intracardiac electrocardiograms, regarded as direct leads from the endocardial surface of the heart, have been obtained by cardiac catheterization, a small German silver electrode attached to the catheter serving as the exploring electrode.[31, 35, 38] The site of the catheter electrode is determined by fluoroscopy, pressure recordings and oximetry. The usefulness of intracardiac electrocardiography has been chiefly limited to research, especially with respect to our understanding of the genesis of the electrocardiogram.

Intrabronchial electrocardiograms[40, 8] have likewise been studied, but only for research.

Fetal Electrocardiography[69, 49]

An electrocardiogram of the human fetus in utero may be recorded after the fourth month of pregnancy, but not with regularity until after the sixth month. A preamplifier must be used with the conventional electrocardiograph, or an electroencephalograph may serve to record the electromotive forces generated by the fetal heart. Two abdominal electrodes may be used for a bipolar lead, or Wilson's central terminal may be employed as the indifferent electrode while the exploring electrode is applied successively over various parts of the abdominal wall of the mother. The electrocardiograph is standardized so that 1 millivolt causes a deflection of 10 cm. Fetal electrocardiography may be of value chiefly for the diagnosis or verification of fetal life.

The fetal electrocardiogram is characterized by small monophasic or diphasic deflections normally at the rate of 140–150 per minute, interrupted by maternal complexes. Sinus arrhythmia and premature contractions are not uncommon, and occasional instances of fetal atrial fibrillation and heart block have been reported.[24, ■]

THE NORMAL ELECTROCARDIOGRAM AND ITS GENESIS

The electrocardiogram of the human heart is composed of a series of waves designated in succession by the letters P, Q, R, S, T and U.[8, 83, 46, 87, 17] The horizontal portions of the record (isoelectric line) are called segments, which are designated by the letters of the preceding and following waves, e.g., P-R segment, R-T segment or S-T segment. The distance or time *interval* between the waves is measured in seconds from the beginning of one wave to the beginning of the next. Electrocardiographic paper is marked off by vertical time lines and the paper is fed at such a rate that the interval between two fine vertical lines is 0.04 sec.; every fifth vertical line is darker and marks off 0.2 sec. Horizontal lines above and below the isoelectric or base line are 1 mm. apart and serve to measure the electromotive force or potential difference represented by the various waves. The electrocardiograph is standardized so that the curve is deflected upward by 10 mm. when 1 millivolt is added to the circuit. Consequently, the amplitude of any wave can be measured in millimeters or millivolts, 10 mm. representing one millivolt. For facilitating measurements every fifth horizontal line on the electrocardiograph paper is wider and

darker and the distance between two such lines is 5 mm or 0 5 millivolt

The P Wave

The P wave represents the spread of the impulse (depolarization or wave of accession) from the sinoatrial node tangentially along the atrial walls, and to the atrioventricular node, at the approximate rate of 500 mm per sec [ ] The right atrium is activated 01 sec before the left A positive charge (source) precedes this activation wave or band of dipoles while a negative charge (sink) remains behind in the activated muscle A difference of 50 to 100 millivolts may exist between polarized and depolarized adjacent fibers The amplitude and polarity of the P wave depend in part on the direction and magnitude of the depolarization wave but also on the position of the electrodes on the body's surface (points in the heart's electrical field) from which the electrocardiographic leads are taken As *indicated above a positive or upright wave* will be inscribed when the electrode is facing the positive pole of the doublet i e, the on coming accession wave, and a negative or inverted wave when the electrode is so placed that it faces the negative charge i e when the accession wave is moving away from the electrode

The amplitude of the P wave is determined in part by the strength of the electromotive charges developing in the atrial muscle But for any given heart the amplitude of the P wave will be larger the more nearly the lead line from the activated atrium to the electrode parallels the direction of the mean electrical axis of atrial depolarization The *mean electrical axis* refers to the average direction of the electromotive forces generated during depolarization (or during repolarization) There is no P wave or P may be termed iso electric when the lead line is perpendicular to the mean electrical axis of atrial depolarization The first portion of the P wave represents chiefly right atrial, and the latter portion of the P chiefly left atrial activation [58]

The P waves are usually upright in leads aVL and aVF since the electrodes on these extremities face the positive charges of the oncoming depolarization wave whereas P in aVR is negative since the wave is moving away from the electrode on the right arm The greatest amplitude of P is usually in aVF since this lead is most nearly parallel to the mean electrical axis Corresponding to these findings the P wave is usually upright in leads I and II but may be upright, diphasic isoelectric or inverted in lead III since the P in these leads is the difference between the P waves in two of the unipolar limb leads The P wave may be negative but is usually diphasic and of low voltage in V_1 and sometimes in V_2, since it is initially positive as the right atrial activation wave approaches the electrode and later negative as the activation wave moves away from the electrode to activate the left atrium A P wave is abnormally high if it exceeds 3 mm in the bipolar extremity leads or 2 5 mm in the precordial or augmented unipolar limb leads, and abnormally broad if its duration exceeds 0 10 sec Normally the height of the P wave varies between 0 5 mm and 2 5 mm but is less than 2 mm in leads I and III [31] [ ] An increase in amplitude or width of the P wave is usually associated with atrial hypertrophy or dila *tation[73] as is observed notably in cases of* mitral stenosis atrial septal defect tetralogy of Fallot and cor pulmonale

Repolarization of the atria is represented by an atrial T wave (T_P or T) following the P wave and opposite in direction to the P wave The atrial T wave is usually invisible in conventional electrocardiograms either because of low amplitude or because it is concealed within the QRS complex It may occur after the R wave and cause a slight depression of the S T segment

The P Q or P R Interval

The P-Q or P R interval is measured from the beginning of the P wave to the beginning of the Q wave or to the beginning of the R if no Q wave is present The P Q segment from the end of P to the onset of Q represents the delay in transmission of the impulse from atria to ventricles in the bundle of His but chiefly in the atrioventricular node The atrial T wave (T_P) is usually hidden in this segment but may be visible if the P R interval is prolonged In adults with cardiac rates between 60 and 80 per minute the P R interval ranges between 0 12 and 0 20 second,[60] although occasionally rates up to 0 22 may be noted in apparently normal hearts [ ] [ ] [54] When the P R interval appears prolonged the measurement should be checked by subtracting the longest QRS interval in standard leads from the longest P S interval in these leads With more rapid cardiac rates of 100–120 per minute, 0 18 or 0 19 is the upper limit of normal

This relationship between the P-R interval and cardiac rate has been questioned.[60, 61] The P-R interval tends to increase with age, the upper limit of normal being 0.16 in children,[1] 0.18 in adolescents and 0.2 second in adults.[87, illegible] The P-R interval is abnormally short if it is 0.1 second or less. This is observed in the Wolff-Parkinson-White syndrome (p. 106) and nodal rhythm (p. 328).

The QRS Complex

The QRS complex, also termed the initial ventricular deflection, represents depolarization of the ventricle. The Q wave is the first negative deflection and the R wave the first positive deflection of the complex. A downward deflection following the R wave is termed an S wave. A second upward deflection after an S wave is called R' and a second downward deflection S'. If the entire complex consists of only one downward deflection, it is termed a QS wave. Capital or lower case letters are used to indicate large or small waves respectively, a small wave being defined as one which does not exceed half the amplitude of the tallest wave of the QRS. The Q wave or R wave or both may be absent.

A *Q wave* may occur normally in any lead. When it is present in lead I, it occurs also in precordial leads to the left of the interventricular septum. Its mean depth is usually less than 0.5 mm. in standard leads in adults with a maximum depth of 2 mm. in lead I and 3 mm. in leads II and III.[17, illegible, 73] In children and infants the Q wave is normally deeper.[70, 87] In aVR in adults the mean value of Q is about 2.5 mm. A Q wave is regarded as prolonged if its duration is 0.04 second or more except when QS forms the entire initial ventricular complex.[5]

The *duration of the QRS waves*, measured in the limb lead with the widest QRS from the beginning of the Q to the end of the last wave of the complex, usually ranges between 0.06 and 0.08 second, and does not exceed [illegible].10 second normally. Occasionally a QRS interval of 0.11 second or even 0.12 second may occur in a subject with an apparently normal heart. The QRS interval is usually shorter in children (0.04 to 0.08 below the age of 5, and 0.05 to 0.09 between 5 and 14); the QRS interval also diminishes slightly with increasing cardiac rate.[61]

The amplitude of the tallest wave of the QRS complex should measure 6 mm. (0.[illegible] millivolt) or more in at least one of the standard limb leads. The tallest R wave is usually between 5 and 15 mm. in amplitude, with maximal values up to 28 mm. in the standard leads in normal adults.[illegible, 73, 67, 4, 17, illegible] In the precordial leads, the mean height of the R wave ranges between 3 mm. and 14 mm., the tallest usually in V_4 or V_5 and the lowest in V_1. The voltage of the QRS is regarded as high if the highest QRS deflection exceeds 25 mm. (2.5 microvolts) in the bipolar extremity leads, 20 mm. in the augmented unipolar limb leads or 50 mm. in any of the conventional precordial leads.[67, 4, 17, 87] Low voltage of the QRS denotes that the highest deflection is less than 5 mm. in the limb leads and less than 10 mm. in the precordial leads.

The QRS in Limb Leads. The normal electrocardiographic pattern of the QRS complex in the unipolar and standard limb leads varies with the electrical axis of the heart. Usually in aVR there is an rS or Qr pattern, rarely an RSR' or QS pattern with unusual position of the heart. T is normally inverted.

When aVL faces the epicardial surface of the left ventricle, it shows a qR or qRs pattern and T is usually upright. When it faces the epicardial surface of the right ventricle, as it does in a vertical or clockwise rotated heart, it shows an rS, RS or QS pattern, T is usually upward but may be inverted. The more nearly parallel the lead is to the electrical axis, the taller the main positive deflection if it faces the left ventricle, the deeper the main negative deflection if it faces the epicardium of the right ventricle. In a similar manner, lead aVF is more likely to face the left ventricular epicardium and show a qR or qRs pattern, the more vertical or clockwise rotated is the electrical axis of the heart, and it is more likely to face the right ventricular epicardium and show an rS or RS pattern, the more nearly transverse or counterclockwise is the electrical axis of the heart.

The standard limb leads show patterns which are the summations of the findings in the corresponding unipolar limb leads. The major deflections are upright in all three standard leads in hearts which tend to be vertical, but S_1 (the S wave in lead I) tends to become deeper than R_1 and R_3 taller than R_1 the more nearly vertical is the heart. In the normal heart tending toward the transverse position, there is apt to be a Q wave but no S wave in lead I, R_1 tends to be taller

than R_3, and there is a deep S wave in lead III and sometimes in lead II There may be a W shaped QRS of low voltage in lead III T is upright, but may be inverted in lead III especially as the heart tends to be transverse

Time of Intrinsicoid Deflection (QR Interval) The interval from the onset of the QRS complex to the peak of the R wave (intrinsicoid deflection) is usually about 0 02 second with a maximum of 0 03 second in right precordial leads (V_1 and V_2) while in left precordial leads it is usually about 0 03 to 0 04 second with a maximum of 0 05 second[67] The longer interval in leads overlying the left ventricle is presumably due to the longer period required for the impulse to traverse the greater thickness of the left ventricle If two peaks are present RR' the one with the largest downstroke is considered to be the characteristic intrinsicoid deflection

QRS Complex in Precordial Leads[76, 80, 81, 67, 4, 86, 87] The findings in precordial leads suggest that local underlying myocardial areas strongly influence the electrocardiogram because of the profound alterations that may occur with relatively small changes in the site of electrode placement but vectorcardiographic theory regards the former alterations as resulting from changes in the summation vector determined by total cardiac activity from moment to moment (p 33) Leads V_{3R} V_E V_1 and V_2 are termed right precordial leads facing the epicardial surface of the right ventricle There is a small r and a deeper S in V_1 and V_2 but no Q The R wave increases progressively in amplitude in leads further to the left

When the R wave is equal in amplitude to the S wave the so-called transition between right and left ventricular potential has been reached, usually in V_3 or V_4 At this point the lead is perpendicular to the mean electrical axis From V_4 to V_6 there is usually a gradual rise in the height of the R wave and a fall in the S wave with disappearance of the S in V_5 or V_6 A Q wave is often present in V_5 and/or V_6 Occasionally with rotation of the heart positive left ventricular potentials are not dominant until V_7 or V_8 and, conversely the potentials usually associated with right precordial leads may be found only when the electrode is far to the right as at V_{3R}

A Q wave is ordinarily absent in V_1 to V_3 but often appears as a small wave in V_5 or V_6 The Q wave is due to septal activation and appears in leads from the left side of the heart since the septum is initially activated from left to right i e the activation front moves away from the left precordial electrodes[88]

V_1 may disclose a small R wave if septal activation proceeds toward the electrode, or R may be absent if septal activation proceeds perpendicularly to the lead line from the electrode S is present and relatively large Normally R in V_1 does not exceed 7 mm (0 7 mv) and averages 3 5 to 5 mm while S averages between 10 to 12 mm The R/S ratio is less than 1 T may be inverted, isoelectric or upright

V_2 usually possesses an R wave larger than R in V_1 if present, since it is in more direct line with the septal activation wave There is an S wave which is deeper than that in V_1 if the heart is rotated counterclockwise smaller if the heart is rotated clockwise The T wave is upright in leads V_2 to V_6 in adults whereas in children and some young adults T may be inverted normally in V_1 to V_4

V_3 shows progressive increase in the height of R unless there is an anteroseptal infarct left ventricular hypertrophy or left bundle branch block The S wave decreases R is larger than S in vertical hearts smaller than S in horizontal hearts

V_4 reveals that R has become taller than S especially if the apex is relatively anterior S does not disappear until the electrode is over the last portion of the ventricle to be activated, i e , in leads further to the left

V_5 and V_6 show a large R which may occasionally be smaller than R in V_4 S is usually absent

Genesis of the QRS Complex[76, 80] The theories invoked above to explain depolarization of a cell (p 18) or of a single muscle fiber (p 19) may be applied also to an exposition of the genesis of the QRS complex associated with activation of the ventricles The heart may be regarded as analogous to a polarized cell The ventricles are perceived as an irregular U shaped shell formed by the free walls of the ventricles partitioned by the interventricular septum and open at the base in the region of the valves (Fig 15)

The cardiac impulse or excitation wave, initiated normally in the sinoatrial node having traversed the atria, the atrioventricular node and bundle of His spreads through the right and left bundle branches and the ramifications of the Purkinje network

of the conduction system in the subendocardial regions of the two ventricles almost simultaneously. The excitation wave then traverses the ventricular muscle perpendicularly from endocardial to epicardial surface, much less rapidly (approximately 400 mm. per second) than it spreads through the septum and Purkinje fibers (approximately 4000 mm. per second). Recent studies of the spread of activation in the left ventricular wall of the dog[64, 84, 19] indicate that the inner third is activated more or less synchronously, the impulse traveling at the rate of 2000 mm. per second or more; needle electrodes in the inner third of the ventricle yield QS complexes identical with those from the cavity, whereas RS complexes arise in the outer portion of the ventricle. The muscle

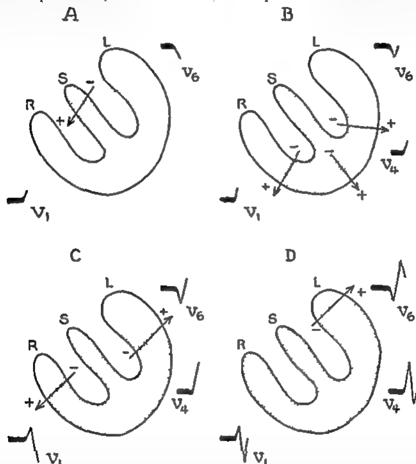

Fig. 15. Ventricular depolarization. Diagram of heart and electrical field in horizontal plane. R, Free wall of right ventricle; L, of left ventricle; S, septum. Stippled area, activated muscle (negative). Arrows indicate direction of activation wave. A, B, C, D, Successive stages in ventricular depolarization.

A, Onset ventricular depolarization. Septum depolarized from left to right. Positive upward deflection in right precordial lead (V_1) toward which activation wave is directed. Downward deflection in left precordial lead (V_6).

B, Septum, apex of left ventricle, part of free wall of right ventricle depolarized. Activation of right ventricle toward right continues positive wave in right precordial lead. Beginning activation of left ventricle may give small positive deflection in V_4, but activation wave is still directed away from or perpendicular to V_6. Therefore no upright deflection in V_6.

C, Septum and right ventricle depolarized. Left ventricle largely depolarized with activation wave of maximal cross-sectional area directed to the left. Maximal upright (R) wave in V_4, somewhat less in V_6. Negative deflection in right precordial lead V_1 as stronger electromotive forces of left ventricle overbalance right ventricular electromotive forces.

D, Depolarization completed in septum and right ventricle. Last phase of depolarization of basal portion of lateral wall of left ventricle. Activation wave directed to left but cross-sectional area diminished. At V_4 negative (S) wave as activation wave moves away from overlying electrode. At V_6 no S wave as depolarization will finish in this area. At V_1, V_4, V_6, R and S return to isoelectric line as cross section of activation wave diminishes.

mass of the left ventricle, being larger and thicker than the right develops greater electromotive forces and requires more time for depolarization than the right ventricle

The direction and magnitude of the electrical axis are continually changing from instant to instant as the process of ventricular depolarization progresses The appearance of the QRS complex in terms of direction and magnitude of the individual waves is determined by these changes in direction and magnitude of the activation wave (i e, its electrical axis) and by their relation to the site of the electrode from which the electrocardiogram is registering potential differences The major deflection of the QRS will be upright (positive polarity) when the activation wave is moving toward the recording electrode, downward (negative polarity) when the activation wave is moving away from the recording electrode

In the initial phase of depolarization the wave of activation traverses the interventricular septum from the left to the right side (Fig 15*A*) An electrode on the right side of the precordium (lead V_1) will record an upright wave since it faces the positive charge of the approaching activation wave An electrode on the left side of the precordium (leads V_5 and V_6) records a small negative wave the Q wave, because the septal activation wave from right to left is moving away from these electrodes Electrodes which are intermediate in position may record no wave at this moment since the lead lines from these electrodes to the activation wave are perpendicular to the electrical axis of the activation wave

With the spread of the impulse the entire septum, *the apex and much of the free wall of* the right ventricle are activated (Fig 15*B*) The electrical axis is still directed to the right and the right precordial leads (V_1) record a positive wave Its amplitude depends on the degree to which the positive electromotive forces directed toward the right electrodes overbalance the negative electromotive forces from the activated apical portion of the left ventricle which are directed away from V_1 The early activation of the left ventricle now produces electromotive forces directed to the left and records the onset of an upright (R) wave in left precordial leads

As activation of the right ventricle is being completed and the free wall of the left ventricle becomes almost completely depolarized (Fig 15*C*), the predominant electromotive forces and therefore the electrical axis are directed to the left Therefore leads from electrodes on the right arm (aVR) and right precordial leads (V_1 and V_2) show a downward deflection (S) since the predominant left ventricular accession wave is moving away from these electrodes as it proceeds from the subendocardial toward the epicardial area of the left ventricle At the same time this activation wave is directed *toward* left precordial electrodes and toward an electrode on the left arm, and a positive or R wave is recorded in leads V_4 to V_6 and in aVL

With complete depolarization of the septum and right ventricle a small portion of the base of the left ventricle remains to be depolarized Activation of this final portion of the left ventricle is associated with electromotive forces from right to left which are directed toward left precordial and left arm leads The activation wave in this last portion of the left ventricle to be depolarized which is recording a *positive (R) wave in V_5 and V_6 may be* moving away from V_4 and therefore recording a negative (S) wave in V_4 No S wave is usually observed in leads from the basal portion of the lateral wall of the left ventricle since this is the last area to be activated and the activation wave does not proceed away from it

It should be noted that this concept of cardiac depolarization (and likewise of repolarizaton) in terms of the dipole wave or band theory is not generally accepted by those who regard *the electrocardiographic* representation of cardiac excitation and recovery as the summation of two somewhat *asynchronous monophasic action potentials* ("interference theory") [18]

The RS T Segment

The S T, R T, or RS-T segment is the segment between the end of the QRS complex and the onset of the T wave It is measured from the end of the S to the beginning of the T wave or from the end of the R if no S wave is present The point marking the end of the QRS is termed the S-T junction or J The RS T segment represents a state of unchanging polarization between the end of depolarization and the beginning of repolarization, or a stage at which terminal depolarization occurs simultaneously with, and is neutralized by, commencing repolarization Electrodes in any part of the heart s electrical field face an equal number of positive and

negative charges and the galvanometer records no electromotive force The RS-T segment of the electrocardiogram is therefore usually isoelectric and lies flat along the base line, but slight elevations are normal and not uncommon

The S-T segment is displaced or deviated from the baseline whenever complete depolarization is delayed and an increase in repolarization has occurred before depolarization is completed in one or both ventricles To determine RS-T displacement the level of the S-T segment is compared with that of the following T-P segment and not with the preceding P-R segment[8] This will prevent an erroneous diagnosis of S-T deviation when the S-T segment is compared with a P-R level which is deviated by a T_P (atrial T) wave An elevation or depression of less than 1 mm in the standard leads is generally regarded as within normal limits Since the normal tendency is for the RS-T segment to be isoelectric or slightly elevated in precordial leads a depression of even 0.5 mm may be abnormal while a similar degree of elevation is not Accurate measurement of an elevation or depression of the S-T segment requires that the baseline or isoelectric level should not be drifting from the horizontal

The duration of the S-T segment increases with slowing of the heart rate and varies from 0 10 second when the rate is 100 per minute to 0 15 second at a rate of 50 per minute The S-T segment is slightly longer in women than in men or children In precordial leads the S-T segment is usually very short or absent because of earlier recording of repolarization in these leads The repolarization which begins in small areas before completion of depolarization is not as apt to be recorded in the more distant unipolar limb or standard leads The S-T segment in precordial leads may be depressed normally as much as 1 mm but more frequently it is elevated to as much as 2 mm or more above the isoelectric level When T is tall there is more apt to be an elevation of the RS-T segment but this elevation does not exceed one quarter the height of the T wave

Abnormal RS-T deviation (elevation or depression) may occur in a variety of conditions but notably with acute myocardial infarction subendocardial ischemia or infarction, acute pericarditis digitalis drug ventricular hypertrophy, ventricular aneurysm tachycardia, hypopotassemia and other electrolyte disturbances

The T Wave

This wave represents ventricular repolarization and occurs during the latter part of systole It is normally upright in leads I and II upright or inverted in lead III Its height averages 3 mm in lead II, 2 mm in lead I and 1 mm in lead III In precordial leads the T wave usually ranges between 3 and 8 mm in height, being somewhat taller in men than in women High voltage of the T wave denotes that its height exceeds 7 mm (0 7 millivolt) in any bipolar extremity lead, 5 mm in any augmented unipolar limb lead or 20 mm in any precordial lead[17] Low voltage of the T wave is indicated when the highest T wave is less than 1 mm in all the extremity leads and less than 2 mm in all the usually recorded precordial leads In lead I a T wave which is less than 0 5 mm in height or a negative T wave is abnormal A negative T wave in lead II in the supine subject is usually abnormal but T is often inverted normally in lead III, especially in obese patients and those with a transversely placed heart T is usually inverted in aVR, usually positive up to 4 mm in aVL but occasionally inverted 1 to 2 mm, usually upright up to 5 mm in aVF but occasionally negative by 1 mm In children the T wave is almost always upright in aVL and aVF The T wave is usually upright in the precordial leads in the adult occasionally inverted in V_1 and less frequently in V_2 to V_4 The T wave is almost always inverted in V_1 and V_2 and often in V_3 in infants and is usually inverted in right precordial leads (V_1) in children and some young adults[73] [illegible] Wasserburger[74] encountered frank inversion of the T waves in the right and midprecordial leads in 10 [illegible] per cent of 131 adult Negro males Because of the resemblance to the negative T waves in infants and young children he termed it the juvenile pattern' and cautioned against interpreting it as evidence of myocardial disease Similar changes could be induced by hyperventilation and abolished by vagal blocking agent [illegible]

A T wave may be inverted in adults in leads I or II or in precordial leads as a result of smoking drinking cold water severe emotional upsets, digitalis drugs insulin, hypopotassemia and hypocalcemia beriberi, hyperthyroidism and myxedema, and as the result of hyperventilation[75] The T wave is inverted

in lead I, aVL and left precordial leads in connection with left ventricular hypertrophy and in leads II and III and often in right precordial leads in right ventricular hypertrophy. Inverted T waves in leads I, II or III or in unipolar or precordial leads may be due to myocardial disease, especially myocardial infarction, coronary insufficiency of varied etiology and in bundle branch block.

It was previously mentioned that in a uniform muscle strip one would anticipate that the wave of repolarization (T wave) would be directed opposite to that of depolarization (QRS), since repolarization should begin in the same region as depolarization and follow the same course. If such uniformity applied to human heart muscle, there would normally be a negative T wave when the QRS was predominantly positive. However, possibly because of a slower rate of metabolism and therefore delayed completion of depolarization in the subendocardial region, repolarization begins in the subepicardial portion of the myocardium and proceeds toward the subendocardium, in opposite direction to depolarization. As a result of this lack of ventricular uniformity and consequent differences in intensity and duration of depolarization in different ventricular areas (ventricular gradient, p. 51), the T wave is in the same direction as the major deflection of the QRS.

The Q-T Interval

The Q-T interval represents the duration of ventricular electrical systole including depolarization and repolarization. It is measured from the beginning of the QRS to the end of the T wave, preferably in the lead showing the tallest and most distinct T wave termination. Accurate measurement is often impossible when the T wave is low, when the U wave is well developed, when the end of the former and beginning of the latter are indistinct, and when P and T are superimposed.[71, 45] Accurate measurement is also difficult or impossible in the presence of bundle branch block or ventricular arrhythmias. Accuracy may be increased by taking the average duration of several or many Q-T intervals. The Q-T interval is most accurate in the lead in which it is most clearly demarcated and usually in which it is longest. The Q-T interval varies with the heart rate, increasing as the latter slows. The Q-T interval is somewhat shorter for men and children than for women.

The normal Q-T interval for a given cardiac rate may be calculated from Bazett's formula.[9] Normal Q-T = $K\sqrt{R\text{-}R}$, in which K is a constant equal to .37 for men and children and .40 for women and R-R represents the interval between two R waves. The ratio between the measured Q-T interval and this calculated normal Q-T interval is sometimes termed the Q-T ratio. A corrected Q-T interval, QT_c, has been employed by Taran and Szilagyi,[71] $QT_c = \frac{\text{Q-T (as measured)}}{\sqrt{R\text{-}R}}$. The upper limit of normal of the QT_c is said to be 0.405. However, a variety of other formulae have been promulgated to determine the normal Q-T interval and the values obtained differ significantly, especially when the cardiac rate is somewhat above or below the most common normal range.[11, 4, 1] Values between 0.425 and 0.445 have been given as the upper limit of normal. In view of the difficulties in measuring the Q-T interval and disagreement as to its normal range, one should be cautious in utilizing it as a diagnostic sign.

The Q-T interval may appear prolonged because of increased duration of the QRS, of the S-T segment or of the T wave or because of erroneous inclusion of the U wave. The adjusted Q-T interval is the measured Q-T less the duration by which the QRS is prolonged. It indicates whether there is an abnormality in the Q-T interval due to repolarization.

A prolonged Q-T interval occurs in hypocalcemia, in uremia probably because of hypocalcemia, and in hypokalemia. In hypocalcemia the prolongation appears to concern chiefly the S-T segment, in hypokalemia the T wave duration. In hypokalemia the apparent prolongation may be due to the presence of a distinct U wave which may be difficult to differentiate from the T. Similarly, prolongation of the Q-T interval, which may occur after quinidine or atabrine, or after a cerebrovascular accident,[9] may also be due to the presence of a *U* wave. Less marked prolongation of the Q-T interval may be associated with rheumatic and other myocardial disease, myocarditis, pericarditis, pulmonary embolism, beriberi and myxedema.

The Q-T interval may be shortened after digitalis drugs, in hypercalcemia and hyper

kalemia (conditions causing subendocardial anoxia and a diminished ventricular gradient) and by increased vagal tone (adolescence)

The U Wave

The U wave is a low broad wave usually not exceeding 0.5 mm in height in standard leads. It is present in the standard leads in the majority of subjects. It occurs 0.02 to 0.04 second after the T wave and its duration is about 0.2 second.[55]

A prominent or widened U wave occurs with hypokalemia, with quinidine, digitalis and epinephrine administration and in a variety of conditions. A negative U has been observed with variable frequency in cases of hypertension and left ventricular hypertrophy and occasionally with myocardial infarction.

The origin of the U wave is unknown. It has been interpreted as corresponding with the after potential in nerve since the U wave occurs coincident with the supernormal phase of ventricular excitability. It has also been attributed to the mechanical effect of ventricular distention during the early phase of rapid filling.

VECTORCARDIOGRAPHY (VECTOR ELECTROCARDIOGRAPHY)

Relationship Between Electrocardiography and Vectorcardiography

The electrocardiogram records the electromotive forces generated by the heart from moment to moment as projected onto various sites of the body's surface. The electrocardiogram is a scalar delineation of these forces since it represents only the magnitude (voltage) and sense (positivity or negativity) but not the direction of these forces. On the other hand, a vector is an entity possessing not only magnitude and sense but also direction. A vector is generally represented by a straight line in the form of an arrow, its length denoting magnitude, the arrow head pointing its direction, and the position of the arrow with respect to some axis of reference indicating positivity and negativity.

The electromotive forces generated by the heart from instant to instant may be recorded as vectors.[111] These instantaneous vectors of the electrical activity of the heart may be represented on some coordinate axial system by a successive series of arrows whose origin is at the same zero point in the axial system but whose direction, magnitude and sense may change from moment to moment in the course of a single cardiac cycle. A curve joining the terminus or arrowhead of these vectors forms a loop which is known as a *vectorcardiogram*.

The vectorcardiogram is merely a different form of representation of the same cardiac electromotive forces as are depicted by the electrocardiogram. In the electrocardiogram these electromotive forces are delineated as a scalar function of time; in the vectorcardiogram, as a vector function of time. The electrocardiogram records the potential difference (voltage) from instant to instant at a given *point* on the body surface relative to some other *point*; each record represents a *single lead*. The conventional vectorcardiogram records the projection of the heart's electromotive forces on a *plane* of the body surface; each record represents the resultant of two or more leads in that plane. The electrocardiographic leads in any plane can be determined from the vectorcardiogram projected on that plane; conversely, the plane vectorcardiogram can be determined and in practice is actually determined from two leads in that plane. Neither is subservient to the other. As indicated, both the vectorcardiogram and the electrocardiogram are graphic records of the projections on a plane or on a line, respectively, of the same electromotive forces. On the other hand, even when electrocardiographic leads are recorded simultaneously and from the same electrode sites as the vectorcardiogram, neither the electrocardiogram nor the planar vectorcardiogram constructed manually from any two electrocardiographic leads provides as much information as the vectorcardiogram taken from the same electrode sites by the cathode ray vectorcardiograph machine. This is owing in part to the relatively low film or paper speed of the electrocardiogram compared to the cathode ray trace of the vector loop, which is far more accurate and detailed from instant to instant.

The basic tenet of vectorcardiography is that all the electrocardiographic leads recorded in man are derivatives of the spatial cardiac vector, i.e., projections of the vector on the individual leads.[110, 119, 120, 136] Furthermore, the potential differences recorded at any electrode site from moment to moment are determined by the summation of all the

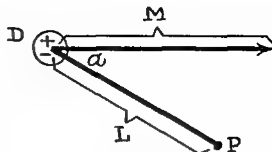
electromotive forces generated by all parts of the heart from moment to moment, i.e., by the spatial vector, they are not essentially or chiefly reflections of local subjacent myocardial potentials (proximity potentials). On the other hand, according to the concept advanced particularly by Wilson,[147, 150] unipolar precordial leads are semidirect leads and are determined largely by local electromotive forces generated in the subjacent region of the myocardium.[16] Thus right precordial leads are considered to be determined to an important degree by the underlying right ventricle. The occurrence of localized changes in the precordial leads has been regarded as evidence supporting the Wilson concept of proximity potentials. However, corresponding mirror image electrocardiographic changes observed in electrocardiograms recorded from a distant and predictable site,[14] cast doubt on the concept of a localized generation of the local precordial pattern and favor the concept that the changes represent the projection at the electrode site of the spatial cardiac vector.

The Spatial Cardiac Vector

Since the heart which generates the electromotive forces and the surrounding conducting tissues (volume conductor) is three dimensional, the vector representing these forces is oriented in three dimensional space, not in a single plane. In other words, the instantaneous vectors of cardiac electrical activity are spatial vectors and their ends may be represented by a loop which lies in three-dimensional space. We have no method of directly recording these actual instantaneous spatial vectors or the loop formed by these vectors, although devices are available for direct visualization of the three-dimensional relationships of the planar vectorcardiograms, or for direct stereoscopic recording of the vectorcardiogram.[105, 111] If our assumptions underlying vectorcardiography are correct, there is only a single actual spatial vectorcardiogram of a given heart at a given time, and the spatial vectorcardiogram determined from the vectorcardiograms in any two planes should have the identical magnitude, sense and direction regardless of electrode placement or other technicalities of the different methods of vectorcardiography.

By means of electrodes arbitrarily placed within the electrical field of the contracting heart, i.e., on the body surface and connected to appropriate recording galvanometers, we tap and record that component of the actual spatial vector which is directed toward the electrodes in question. The recorded component of the spatial vector is modified by the distance from the actual electromotive forces represented by the spatial vector and by the intervening conducting media, as well as by the instrumental devices for receiving and recording the electrical forces. For these reasons neither conventional electrocardiograms nor vectorcardiograms as now determined can be regarded as the true representation of the actual cardiac electrical forces, since these curves are dependent largely on the position of the receiving electrodes which only pick up a modified component of the actual instantaneous spatial vectors. Different systems of vectorcardiography represent different components of the true vector depending on their differences in electrode placement. Like many objects in space, the actual spatial vector may appear different when viewed from different directions; the actual spatial vector, if it could be determined, like the object viewed, should remain the same. Spatial vectorcardiography, as now practiced, refers to the representation of vector loops as projected onto multiple planes, usually the frontal, horizontal and sagittal. The spatial vector may be constructed from these planar vectors, but such constructions do not yield the true spatial vector, probably because some of the premises underlying the various techniques of vectorcardiography are more or less inaccurate (p. 44).

The symbol for spatial vector of the electrical forces of the heart is $s\hat{E}$, s for spatial, E for electrical forces, and the arrow head to denote a vector quantity. The spatial vector loop representing the ventricular electrical forces of depolarization is indicated by QRS $s\hat{E}$ loop, the spatial loop of repolarization by T $s\hat{E}$ loop, and the spatial loop of atrial depolarization by P$s\hat{E}$ loop.[illegible] The symbol s is omitted when referring to the planar vector loops, e.g., the horizontal plane QRS $\hat{E}$ loop.



The Dipole Theory and Vectorcardiography

The electrophysiologic basis of the electrocardiogram described above (p. 18) applies equally to the vectorcardiogram with some change in terminology. A dipole has been defined as a pair of electrical charges of equal strength and opposite polarity, a

finite distance apart When a dipole is placed in a conducting medium (volume conductor) it produces an electrical field in that conductor Vectorcardiography is based on the premise that the electrical behavior of the heart and its effect on the surrounding body tissues are analogous to those of a dipole in a volume conductor

For the purpose of calculating the electrical potential at any point in the electrical field produced by a dipole in a volume conductor, we define the vector of the dipole as a vector whose direction is indicated by an axis drawn through the poles from the negative to the positive and whose magnitude is equal to the product of one of the charges by the distance between the two charges (poles)[110] Then the electrical potential at any point P in the electrical field (relative to a distant point) (Fig 16) is computed as being proportional to the magnitude of the dipole vector (M) multiplied by the cosine of the angle formed by the dipole vector and a line drawn from the dipole to point P (angle alpha) and inversely proportional to the square of the distance of point P from the dipole (L) It is essential to stress that this computation may be applied only if the distance between the charges of the dipole is small relative to the distance of point P from the dipole If the line from the dipole to point P is a right angle the electrical potential is zero as the angle alpha diminishes from 90 to 0 or increases from 90 to 180 degrees the potential increases correspondingly but with different polarity

In the course of depolarization and repolarization of the innumerable cardiac fibers not one but multiple dipoles are formed[1,2] However if there are many dipoles in a volume conductor the individual dipole vectors may be added by the parallelogram law to give a single total dipole vector Then at any point P in the electrical field produced by such multiple dipoles, the electrical potential (relative to a distant point) may be computed from this total dipole vector in the same way as the potential was shown above to be computed from a single dipole vector In other words the electrical field produced by multiple dipoles within a volume conductor is the same as would be produced by a single dipole whose dipole vector is equal to the sum of the individual dipole vectors But such vectors can be added only when they define concentric dipoles i e, dipoles with the same

Potential at P = $\frac{M \cos alpha}{L^2}$

D = Dipole
P = Point in Volume Conductor
M = Magnitude of Dipole Vector
L = Distance point from Dipole
a = Angle formed by M and L

Fig 16 Electrical potential at point P in an electrical field produced by a dipole (D) in a volume conductor M = magnitude of dipole vector a = angle alpha L = distance of P from dipole Potential at P = $\frac{M \cos alpha}{L^2}$

center Also it must be stressed again that these computations apply only if the distance between the multiple dipoles is negligible compared to the distance from the dipoles to the point P in the volume conductor

Vectorcardiography assumes that the electrical field set up by the hypothesized numerous dipoles of cardiac electrical activity in the tissues surrounding the heart (volume conductor) is the same as that which would be produced by a single dipole whose vector is the sum of these individual dipole vectors Thus the dipole theory applied to vectorcardiography assumes that the potential differences at points where electrodes are placed on the body's surface, i e points in the electrical field, are produced by cardiac activity as if the heart were a single dipole, and that these electrode sites are sufficiently distant from the dipole relative to the distance between the charges of the dipole or relative to the distance between the innumerable dipoles of cardiac activity

The Mean Electrical Axis and Angle of Deviation

It has been mentioned that the numerous electromotive forces generated by cardiac activity in various parts of the heart from moment to moment possess magnitude and direction and may be represented as vectors The resultant of these electromotive forces at

any instant may likewise be represented as a vector and is termed *the instantaneous electrical axis of the heart* The instantaneous axis of greatest magnitude is the major instantaneous axis of the heart The *mean electrical axis* is the representation of the mean magnitude and the average direction of the varied electromotive forces developed throughout depolarization and repolarization [8] Thus the mean electrical axis is determined by the duration as well as the amplitude of the electromotive forces The mean electrical axis of the QRS complex is the average of the instantaneous electrical axes of the QRS, the mean electrical axis of the T wave may be similarly considered The mean electrical axis of the heart is a vector in three-dimensional space (spatial vector s$\hat{E}$) but conventionally we have been concerned with the electrical axis as projected onto the frontal plane The major instantaneous electrical axis or the mean electrical axis projected onto the frontal plane may be calculated from the limb leads with the aid of the Einthoven triangle, the vector representation of the axis determined in this manner from the limb leads is termed the *manifest vector* and the voltage of this vector is termed the *manifest potential* [111] The angle (termed alpha) made by this manifest vector in the frontal plane with a horizontal line is called the *angle of deviation* of the electrical axis Einthoven thought that determination of the electrical axis would aid in distinguishing electrocardiographic abnormalities due to changes in cardiac position from those due to intrinsic myocardial disease but it has proved to be chiefly of theoretical value rather than of help in practical diagnosis

Determination of Electrical Axis

Determination of the mean electrical axis of the heart is often approximated by determination of the manifest *maximum instantaneous vector* from the limb leads by means of the Einthoven triangle the triaxial reference system or some other set of coordinates (Fig 17)

1 **Einthoven's Triangle** A circle is circumscribed about the Einthoven equilateral triangle, whose *apices represent the right and* left arms and left leg and whose sides denote the three limb leads The circumference is marked off in degrees with 0° at the three o'clock point and ±180° at the nine o'clock point of a transverse diameter and minus 90° at the upper and plus 90° at the lower end of the vertical diameter The center of the triangle (and circle) is the origin of the line vector representing the maximum instantaneous (or the mean) electrical axis The angle alpha made by the electrical axis with the transverse diameter is the angle of deviation The axis is determined from any two leads but it is best to use those with the most distinct R and S waves Ideally the leads should be taken simultaneously but conventional electrocardiographic leads may be used for rough approximations

The algebraic sums of the maximal amplitudes of R_1 and S_1 in millimeters is plotted on lead I (Fig 18) positive values being marked off from the midpoint of the line toward the 0° end (left arm) and negative values toward the 180° end (right arm) Similarly the algebraic sum of R_3 and S_3 (or R_3 Q_3 and S_3) in millimeters is plotted on the line representing lead III positive values going below and negative values above the center of the line

From these plotted points on any two lead lines perpendiculars are erected on the lead lines and extended until they meet A line drawn from the center of the triangle to this point of intersection is the vector of the maximal instantaneous electrical axis If this line vector is extended to the circumference the axis deviation from the horizontal may be read off the circumference in degrees Similarly the maximal instantaneous axis and angle of deviation of the T wave may be determined

The *mean electrical axis* of the QRS may similarly be determined, but the area of the QRS in any two leads is used instead of the peak amplitude The area of the QRS is measured in microvolt seconds each square of the electrocardiograph paper representing 0 04 microvolt second or 1 unit These areas (divided by time) denote the mean electromotive force of depolarization in those leads Similarly the areas of the T wave in any two leads may be plotted on two sides of the Einthoven triangle and the mean electrical axis of the T wave determined

The normal mean electrical axis lies between *0° and plus 90° Left deviation of the* electrical axis is indicated when angle alpha is between 0° and minus 60° or more while right deviation of the electrical axis is indicated when the angle of deviation is between 90° and 150°

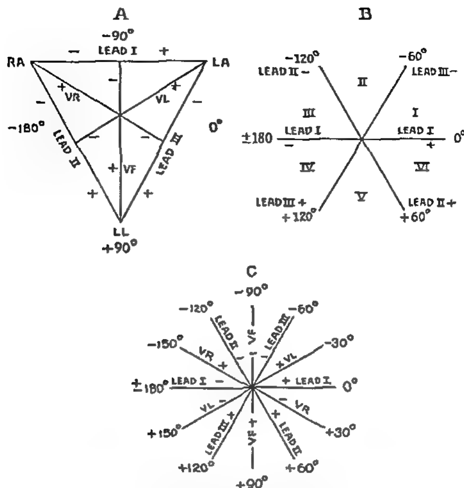


Fig 17 Coordinates to determine electrical axis of heart *A* Einthoven triangle *B* Triaxial reference system *C* Hexaxial reference system to include unipolar limb leads

2 The Triaxial Reference System[93] A circle is drawn with a horizontal diameter and two oblique diameters passing through the center at 60° angles to each other (Fig 19) The three o'clock end of the horizontal line which represents lead I is labeled 0 the nine o'clock end ±180, the oblique diameter running from above downward toward the 0 side represents lead II and is labeled −120 above and 60 below the oblique diameter running from above downward and toward the 180 side represents lead III and is labeled −60° above and 120 below

As directed above in the use of the Einthoven triangle the amplitudes of R_1 and S_1 and of R_3 and S_3 in millimeters are plotted on two of the lead lines beginning at the center of the system and going toward the 0 point or downward for positive values or toward the 180 point or upward for negative values For the mean electrical axis the *areas* of QRS in leads I and III (or leads I and II etc) are similarly plotted Perpendiculars to the lead lines are erected at the plotted points and extended until the perpendiculars intersect The maximal instantaneous axis or the mean electrical axis is represented by the line drawn from the center to this point of intersection Extension of this line to the circumference of a circumscribed circle marked off in degrees will disclose the angle of deviation of the electrical axis

The chart of Dieuaide[107] is also used to determine the mean electrical axis based on the same principles

Derivation of the Vectorcardiogram from the Electrocardiogram

If instead of a single instantaneous axis a series of such axes or vectors were inscribed as above e g every 0 01 second of the de-

B Triaxial reference system with representation of electrical axis of QRS in Fig 19 4 R_1 (13) − Q_1 (1 5) = 11 5 R_2 = 4 5 R_3 (1 0) − S_3 (8) = −7 It is assumed that simultaneous leads were taken The angle of deviation from the horizontal (−10) denotes axis deviation to the left of normal

polarization process (QRS) and the ends of these line vectors were joined the vectorcardiogram loop projection on the frontal plane would be obtained Such a loop can be constructed with the aid of the Einthoven triangle the triaxial reference system or by employing rectangular coordinates[119] The latter may be used to construct the horizontal and sagittal plane as well as frontal plane projection of the spatial vector loop

A simple method of vectorcardiographic derivation from the electrocardiogram utilizes rectangular coordinates i e horizontal and vertical axes crossing each other at right angles The horizontal line is positive to the left of the zero (observer s right) and negative to the right of the zero The vertical line is positive below and negative above the zero

The *frontal plane projection* of the vectorcardiogram may be constructed from lead I (represented on the horizontal axis) and lead aVF (represented on the vertical axis)

The *horizontal plane projection* is constructed on the rectangular coordinates by representing lead I on the horizontal axis and V_1 *on the vertical axis*

The *sagittal plane projection* is constructed on the rectangular coordinates by representing lead V_1 *on the horizontal axis and* aVF on the vertical axis

The vertical lines on electrocardiographic paper mark off intervals of 0 04 second The voltage of the QRS is noted at each 0 01 second if possible or at least at each 0 02 second Thus the voltage at at least four and possibly eight points would be measured if the QRS measured 0 08 second The voltage at the identical moments in each pair of leads is measured and recorded The lead to be represented on the horizontal axis is measured along the left or right according to the polarity and from the point reached on the horizontal axis the voltage in the other lead is now measured up or down on the vertical axis Thus each set of voltages *at identical instants* in the two leads defines a point to the right or left of the vertical and above or below the *horizontal* axis The line drawn *from the zero* to this point represents an instantaneous vector When the several vectors have been constructed at successive moments the line joining their ends is the derived vector loop in the given plane

Various methods have been utilized to derive the vectorcardiogram from the electrocardiogram In general the frontal plane vectorcardiogram has been derived from and correlated with the standard leads or with the unipolar limb leads the horizontal plane vectorcardiogram with the unipolar precordial leads[99] and the sagittal plane vector cardiogram with the esophageal leads

Vectorcardiography by Cathode Ray Oscilloscope

The manual method of deriving the vector cardiogram first employed by Mann[114] (monocardiogram) and modified in various manners by Howard[1 5] Wil on and Johnston[115] Grant and Estes[119] and others is gradually being replaced by use of the cathode ray oscilloscope[119] as practical instruments are devised to obtain direct curves of the vector loops on film Following his early cathode ray oscilloscope to record such loops Mann[131] devised a galvanometer activated by three amplifiers each corresponding to the individual standard leads of the electrocardiogram which reflected a brilliant light spot which could be photographed and recorded as its course described a vector loop Since then progressively improved *cathode ray tubes amplifiers timing* devices and cameras have become available However their clinical usage except for research is still hampered by *their high cost* and insufficient evidence that they provide adequate practical advantages over the electrocardiogram to justify their additional expense and greater difficulty in handling

The cathode ray tube contains a filament which emits electrons and these are attracted to a positively charged grid with an aperture through which the electrons pass and impinge on a fluorescent screen within the cathode ray tube They thus produce a brilliant luminous spot which can be both visualized and photographed In traveling from the grid to the screen the electrons pass between a pair of vertical and a pair of horizontal plates within the tube The beam *of electrons and consequently the luminous* spot is deflected when there is a potential difference between either pair of plates When *the pair of vertical plates is activated by a* potential difference caused by the electromotive forces generated by cardiac contraction the spot is deflected in the horizontal direction (i e the X axis) and when the horizontal pair is activated, the spot is deflected in the vertical direction (Y axis) When both pairs of plates are simultaneously

activated the beam moves obliquely, its orientation to the horizontal (X axis) and vertical (Y axis) being determined by potential differences (voltage) and polarity The plates are so arranged that a positive potential difference produces a downward displacement on one axis or a leftward (or anterior) displacement on the other

The two cables of one of the two bipolar leads determining a plane are connected to an amplifier and thence to the two horizontal plates of the cathode ray oscilloscope Similarly the two cables from the poles of the other bipolar lead after amplification are attached to the two vertical plates of the oscilloscope During the course of cardiac contraction the luminous spot describes a progressive series of dashes which are located various distances above or below the horizontal and to the right or left of the vertical axis of the fluorescent screen of the oscilloscope The whole forms a succession of loops (P QRS and T) beginning and ending at the center as a rule First the P loop then the QRS and finally the T loop are inscribed The P loop formerly poorly inscribed is now being more clearly delineated by newer technical developments A loop is formed corresponding to atrial repolarization as well as one corresponding to atrial depolarization but the former is not satisfactorily recorded at the present time It is apparent that the cathode ray oscilloscope merely adds vectorally the electromotive forces of the two leads and the resulting vector loop derives its properties entirely from those two leads[106] However the technique of vector recording with the oscilloscope provides much more detail from instant to instant than does the conventional form of scalar recording with the electrocardiograph Phase relationship is maintained because the two polar leads are recorded absolutely simultaneously

The two lead connections attached to two pairs of plates result in projection of the cardiac vector in one plane Each pair of leads determining a different plane can be connected successively to the same two pairs of plates the different plane projections being then recorded in succession as the connections to the plates are altered by means of a switch The various pairs of leads may be connected to three pairs of plates in three different cathode ray oscilloscopes to obtain the three plane projections of the vector cardiogram separately There is also available a vectorcardiograph with three amplifiers which feed a triple cathode ray oscilloscopic arrangement, permitting the three plane projections of the cardiac vector to be observed or recorded simultaneously

Because of the relatively small potential differences induced by the heart's electromotive forces amplifiers to increase these voltages 50 000 to 250 000 times are employed with each set of plates in order that the electron beam between the plates should be deflected sufficiently—about ▮ to 4 inches on each axis of the screen For standardization a voltage of one millivolt is introduced into the input circuit of each amplifier and the sensitivity controls so regulated that the desired deflection is obtained A three-step amplification selector permits the choice of optimal amplitude for recording and different amplitudes may be used to delineate the P QRS and T loops Similarly, there are controls to regulate the focusing and intensity of the luminous spot the latter depending on the intensity of the current of electrons forming the beam, which can also be controlled

An electric tuning fork or oscillator circuit provides time-marking by interrupting the vector loop tracing and transforming it into a discontinuous series of dashes Ordinarily there are 300–600 cycles per second for the QRS loop, or more for special study 200 for the T loop and 100 per second for the P loop Interruption at the rate of 500 cycles per second denotes that each dash represents 0 002 second The interrupted segments of the loop are very close together when there is a gradual change in direction and magnitude of the instantaneous vectors and widely spaced when the changes are abrupt Since it is important to know the direction in which the vector loop is being inscribed, the interrupted dashes may be modified to a tear drop or comet shaped pattern with the tail end in the direction of rotation by combining the electrical tuning fork with a relaxation oscillator[146] (an imperfect square wave oscillator)

The permanent recording of the vector projections may be made simultaneously with a 4 by 5 inch cut film camera, with a shutter speed adjusted to 0 5 or 1 second, depending on the cardiac rate The use of 35 mm camera and film is more economical Usually the plane projection vectorcardiogram of a

single cycle is photographed. It is possible to use cameras which *automatically record the* vectorcardiogram as the loops are inscribed. Several still pictures may be recorded per second by means of a cam deflected mirror which follows a continuously moving film and snaps back to its original position through spring action. By disengaging the cam, records can be made on continuously moving film and the temporal relations of successive cardiac phenomena can be recorded. This can be utilized for records of arrhythmias, for distinct separation of the P, QRS and T loops and possibly for clearer delineation of the S-T vectors. Fluorographic emulsions or lino graph paper is suitable for recording. A number of photographic methods have been reported which use special electrical circuits to obtain stereoscopic records directly from cathode ray tubes for better study of spatial vectorcardiograms.

Reference Systems and Electrode Placement

The placement of electrodes is based on the idealized concept that the heart is a point source of electrical potential, that this is at the center of a homogeneous spherical volume conductor composed of the trunk of the body, and that the electrode sites on the surface of the sphere are equidistant from each other and equidistant and electrically remote from the electrical center, i.e., the combined cardiac dipole. Various methods have been described to obtain true orthogonal components of the heart vector, including a mathematical solution for two-dimensional and three-dimensional central terminals[1 5] based on the general theory of heart vector projection.[114] Various spatial geometric reference frames have been visualized, with the electrodes placed on the surface of this sphere in such a manner as to define an equilateral tetrahedron,[151] a cube[1 0] or a rectangle (double cube or rectangular parallelopiped).[110]

The equilateral tetrahedron reference frame has the advantage of employing the same electrode placement electric sites as the standard limb leads to define the frontal plane projection and thus of utilizing the information obtained from the equilateral triangle of Einthoven which is formed by these electrode sites.[90] In the tetrahedron reference frame the apices of the geometric figure are the shoulders and pubis (but the lead electrodes are placed on their extensions onto the right and left arms and left leg as in the standard leads) and the fourth apex (electrode site) is the so-called point of Arrighi, 2 to 3 cm. to the left of the seventh thoracic spine. This position is labeled V_B. The use of the limbs for three of the four electrode sites also provides the advantage of convenience of placement and easy reproducibility of electrode placement. The polarity of this system is so arranged that the positive terminus of the instantaneous vector is registered, i.e., the arrow on the vector points from the negative to the positive, which is from active toward resting cardiac muscle.

The other main reference systems are orthogonal, the component leads being parallel to the natural coordinate axes of the trunk and perpendicular to each other, i.e., the electrodes for the component leads are placed on the thoracic wall in a rectangular arrangement. The common form of orthogonal representation in this country is the cube. The cardiac electrical center in a spherical conductor is regarded as situated at the level of the fourth intercostal space and midway between the anterior and posterior margins of a sagittal plane passing through the body just to the left of the sternum. The cube is formed by eight points on the surface of the sphere (trunk). The electrodes of three bipolar leads are so placed on the thorax as to represent four of the vertices of the cube as equidistant from the electrical center as the anatomy of the body permits, and the connecting leads form three adjoining edges of such a cube.

In the cube reference frame used by Grishman[1 0] (Fig. 20), the *first electrode* with three cable connections is placed in the right posterior axillary line at the level of the second lumbar vertebra (Z^+, X^-, Y^-). This electrode represents one pole of each of the three bipolar leads used to obtain the horizontal, sagittal and frontal plane projections of the cardiac vector. It is not only the positive pole of the vertical (superior-inferior) lead (Z^+–Z^-), but also the negative pole of the sagittal (posteroanterior) lead (Y^+–Y^-) and the negative pole of the horizontal (right to left) lead (X^+–X^-).

The *second electrode* (Z^-) is also placed in the right posterior axillary line, but at a higher level, namely at the level of the right scapular spine, and represents the negative pole of the vertical (superior-inferior) lead.

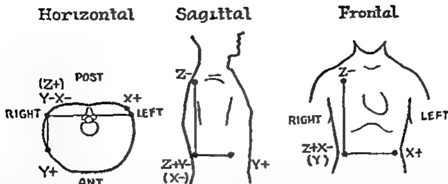

Fig 20 Cube Reference Frame Component bipolar leads of each vectorcardiographic projection showing sites and polarity of electrodes The electrode (X^- Y^- Z^+) is in the posterior axillary line at the level of L [illegible] vertebra and serves for each of the three bipolar leads The electrode X^+ is in the left posterior axillary line at the level L 2 The electrode Y^+ is in the right anterior axillary line at the level L 2 The electrode Z^- is in the right posterior axillary line at the level of the scapular spine Bipolar leads X^+–X^- and Y^+–Y^- determine the horizontal plane projection Y^+–Y^- and Z^+–Z^- the sagittal X^+–X^- and Z^+–Z^- the frontal plane

The *third electrode* (Y^+) is placed in the right anterior axillary line at the same level (L 2) as the first electrode It represents the positive pole of the sagittal (posteroanterior) lead (Y^+–Y^-)

The *fourth electrode* (X^+) is placed in the left posterior axillary line at the level of the second lumbar vertebra It represents the positive pole of the horizontal (right to left) lead (X^+–X^-)

Since in general the normal cardiac vector from negative to positive polarity is directed from right to left from above downward and from behind anteriorly, the electrode which is anterior to to the left of, or inferior to its mate in any bipolar lead is the positive electrode in that pair by arbitrary arrangement Each pair of electrodes determining a bipolar lead is connected with a pair of oscilloscopic plates of corresponding polarity, two bipolar leads (and correspondingly two pairs of plates) determine a given plane

The *frontal plane* of projection of the cardiac vector is determined by the horizontal (right to left) and the vertical (superior inferior) leads the *horizontal plane* by the horizontal (right to left) and sagittal (posterior anterior) leads and the *sagittal plane* by the sagittal (posteroanterior) and vertical (superior inferior) leads The body is viewed from the front for the frontal plane from above for the horizontal plane and from the right side for the sagittal plane projection of the cardiac vector Right left anterior and posterior refer to the body and not to the viewer Similarly in representations of the cardiac vector projections on paper or film, the left side of the body is on the right side of the paper in frontal and horizontal plane projections The lower side of the representation of the horizontal plane projection denotes the anterior aspect of the body, while in sagittal plane projections the right side of the paper denotes the anterior aspect of the body

One of the advantages claimed for the cube and other orthogonal systems of electrode placement is that the horizontal plane projection of the spatial vectorcardiogram conforms fairly closely with that predicted from the precordial lead electrocardiogram and vice versa while the frontal plane projection conforms with the standard lead and the sagittal plane projection with esophageal lead electrocardiograms On the other hand the need to place all the electrodes on the trunk renders this system somewhat less convenient and the site of placement less reproducible than in the tetrahedron system in which three of the leads are in the standard positions on the extremities

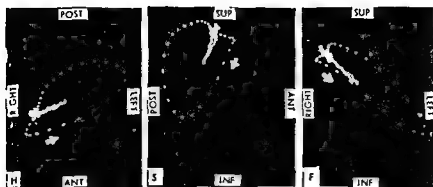
For other reference systems and methods of electrode placement the reader is referred to Duchosal and Sulzer[110], Schellong[140] Burger and van Milaan[10], Donzelot et al [105] The last named obtained vectorcardiograms by using the unipolar lead V_6 as the horizontal lead V_F as the vertical lead and V as the sagittal (posteroanterior) lead V_6 and V_F determined the frontal plane projection V_6 and V_2 the horizontal plane and V_F and V_2 the sagittal plane projection Lamb and Dimond[12] advocated a reference system combining some elements of the tetrahedron and of the orthogonal systems Other devices and

methods of electrode placement have been utilized in an effort to correct or reduce the errors inherent in systems now being used.[90a, 115]

If the different systems are all valid, the spatial vectorcardiogram of any individual at a given time should be invariant regardless of the system used. Nevertheless, considerable differences are found in the form and principal axis of the vector loops, in their spatial orientation, in the quadrants they occupy or in their sense of rotation.[103, 127, 115] As a rule, the differences with the various methods of electrode placement are greater in the horizontal and sagittal plane projections than in the frontal, and more marked in abnormal than in normal hearts.[103, 127]

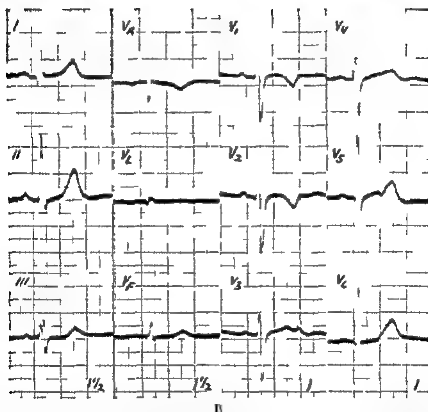
The variations in vectorcardiograms observed with the different reference systems are due to various degrees of inaccuracy in the assumptions underlying vectorcardiography.[114] The heart is not a point source of electrical potential.[114, 14] The electromotive forces are dispersed in the cardiac generator and it is uncertain whether addition vectorially of the multiple electromotive forces permits the establishment of a unitary resultant or vector.[131, 111] If there is a single instantaneous vector, it is uncertain whether its origin is constant or whether it alters its position during the cardiac cycle.[109] Neither the human body nor its trunk is a tetrahedron, cube or parallelopiped, and the electrical position of the heart is eccentric, not in the center of the volume conductor.[139, 113, 117, 136] The conducting tissues (volume conductor) do not form a sphere or other symmetrical geometric figure nor are they homogeneous.[118] Other reasons for differences in the vectorcardiograms depicted by the various systems of electrode placement are: the electrodes are not equidistant from each other, nor are they placed at equal distances from the heart as the methods assume; the dimensions of the heart are not inappreciable relative to the dimensions of the volume conductor, and consequently the electrodes may be insufficiently remote electrically from the heart and may be affected significantly by adjacent local cardiac electromotive forces. These imperfections affect one system of electrode placement more than another or in one respect more than another. These deficiencies should be regarded as imperfections, for the most part quantitative imperfections, but they do not invalidate the entire study of vectorcardiography or any of the major systems of reference, since vectorcardiography is providing a useful body of theoretical and practical information regarding cardiac activity and cardiac disease.[1, 8] The need for universal agreement on a standardized method of electrode placement is apparent, but until the most accurate leads are determined, such standardization may be premature.[illegible]

THE NORMAL VECTORCARDIOGRAM



It is impractical at the present time to set down in detail the appearance or appearances of the normal vectorcardiogram in all the usual plane projections because significant differences are observed with different reference frames and different sites of electrode placement employed in the various systems of vectorcardiography. For the purpose of orientation, however, a brief résumé follows of the usual normal configuration of the vectorcardiogram, based chiefly on the method with which I am most familiar, that utilizing the cube reference frame and electrode position placement of Grishman.[10]

The QRS sÊ Loop



There are three recognizable vectorcardiograph loops, the P, QRS and T, of which the QRS loop is the largest. The QRS loop usually possesses a smooth, narrow, ellipsoid configuration, but is sometimes flattened or indented. It is usually three to four times as long as it is wide. The initial portion is inscribed slowly (markings somewhat closely spaced), the major portion of the loop more rapidly, and the terminal portion relatively slowly. The loop begins and ends at the same central zero point and is therefore closed. It is usually oriented to the left, inferiorly and slightly posteriorly, corresponding somewhat to the anatomic axis of the heart according to Duchosal and Sulzer.[110]

According to Burch et al.,[99, 89] who used the equilateral tetrahedron reference frame, there are two main QRS spatial loop patterns. Almost 90 per cent have a narrow elliptoid configuration with most of the area anterior to the isoelectric point, whereas somewhat more than 10 per cent have a second more complex configuration with length and width more nearly equal and the terminal portion of the loop located posterior to the isoelectric point. This division into two types of patterns is probably an artefact and due to proximity of the back electrode to the heart.[117, 90]

The normal vectorcardiogram with the

A

B

Fig 21 *A* Vectorcardiogram (VCG) of normal adult H horizontal projection S sagittal projection F frontal projection The vectorcardiogram is directed to the left inferiorly and somewhat posteriorly Counterclockwise inscription of QRS loop in horizontal plane (white arrow)
B Electrocardiogram (at 50 mm per second) of same subject

cube reference frame appears as follows[141-146] (Fig 21)

In the *horizontal plane* the loop is inscribed *counterclockwise* beginning with an initial deflection anteriorly and to the right and proceeding thereafter to the left and somewhat posteriorly The long axis in the adult is usually within the −30 to +30 degree segment and more often within the −10 to +10 segment

In the *sagittal plane* (viewing the right lateral aspect of the body) the QRS loop is inscribed *clockwise* and is characterized by a small initial deflection anteriorly and occasionally superiorly but the remainder is directed downward and somewhat posteriorly In the adult the QRS loop is usually oriented in the +90 to +120 degree segment but there is considerable variation and sometimes the QRS loop in this projection is

bizarre and a distinct long axis cannot be determined

In the *frontal plane* the QRS loop is usually inscribed in a clockwise direction when the loop lies within the +30 to +80 degree segment and counterclockwise when the loop lies within the +30 to 0 segment Most frequently the loop lies in the +15 to +70 segment The normal QRS loop in the frontal plane is inscribed to the left and downward but there may be an initial small deflection to the right and superiorly The QRS loop often appears very narrow in this plane and occasionally has a figure 8 configuration

Effect of Age and Respiration During the first week of life the QRS spatial loop is situated to the extreme right and somewhat posteriorly[133 138], in young children it assumes a more anterior orientation ultimately appearing as a vertical loop but extending more anteriorly and to the right than in adults In young children the initial portion may be large and may extend appreciably to the right[141] accounting for prominent R waves in right precordial leads As in adults the inscription of the QRS loop in children by the cube system is counterclockwise in the horizontal and clockwise in the sagittal and *frontal planes* *With advancing age the QRS* loop becomes progressively more horizontal and posteriorly located[1 0 ■]

With inspiration the QRS sÊ loop was reported to shift somewhat posteriorly and with expiration anteriorly[1 0] However Burch et al[101] noted that in pregnancy a deep inspiration caused the maximal vectors to become more anteriorly located The loop also tends to become more vertical with deep inspiration and more horizontal with deep expiration but little change occurs in the configuration of the loop There is evidence that the spatial position of the initial and terminal vectors of the QRS loop varies with the position and degree of rotation of the heart[154]

The T sÊ Loop

The spatial T loop, like that of the QRS, is ellipsoid but narrower and much smaller in size occasionally it is more circular[104 110 141] It is roughly parallel to and usually enclosed by the larger loop (Figs 21–22) The direction of inscription of the T loop is the same as that of the QRS in all three projections but it is inscribed more slowly especially the centrifugal (initial) limb[122]

In the adult the T loop in the cube *reference frame is usually located slightly an*terior to the right and inferior to the QRS loop from which it deviates usually by 10 to 30 degrees, but not more than 50 degrees[111] This constant positional relationship is important since wider divergence often denotes myocardial disease or other abnormality In children this spatial relationship between the T and QRS loops is much more variable than in adults, corresponding to the greater variability of the T wave in the electrocardiogram of children notably in precordial leads The T loop in children usually lies inferior and posterior to the QRS loop The backward direction of the T loop in infants and chil*dren corresponds to the inverted* T waves observed in leads V_1–V_4 In the first 24 hours of life the T vector is directed to the right or is vertical

The P sÊ Loop

Technical difficulties of recording this loop have led to neglect in studying it Conway et al[104] described the P wave as small and irregular or mitten shaped as being slowly inscribed and as occupying a position more or less parallel to the QRS More recently study of the P loop has been made feasible by means *of great amplification e g , at a sensitivity of* 30 to 45 cm /mv instead of the conventional sensitivity of 5 5 to 10 cm /mv Clear images of the P wave have been obtained with the aid of a rapid sequence automatic camera Hellerstein et al[123] have described a technique of selective (differential) vectorcardiography permitting systematic study (dissection) of the component P QRS and ST T loops of the cardiac cycle, which yields clear details of the P loop, as well as of the ST-T and initial and terminal parts of the QRS The vectorcardiograph (oscilloscope) beam is extinguished during all parts of the cardiac cycle except where the selective dissector apparatus unblanks the portion of the vectorcardiogram which is to be inscribed and studied

Studies with the cube reference frame reveal the P wave as a narrow elongated nearly vertical hairpin shaped loop directed downward, beginning and returning to the zero (isoelectric point) (Fig 22) Its direction is little if at all to the left or right of the vertical axis or anterior or posterior to the horizontal axis In the frontal plane the direction of inscription is usually counterclockwise, rarely linear or figure-of eight It is principally

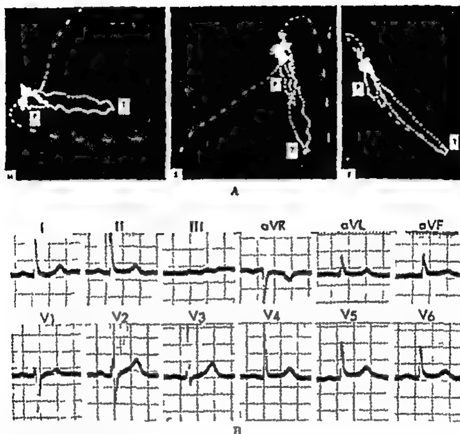


Fig. 27 *A* Vectorcardiogram showing normal P loop of 22 year old girl P loop is directed almost vertically downward and very slightly anteriorly and to the left
B Electrocardiogram in same case

counterclockwise in the horizontal plane In the sagittal plane the inscription is usually clockwise or figure-of-eight In the frontal plane the angle of deviation (alpha) of the major P vector ranged between 60 and 93 degrees with a mean of 78 8° in the series of Fowler and Dorney[112] in the sagittal plane from 70 degrees to 100 degrees with a mean of 84° Thus the inclination is almost straight downward with minimal deviation to the left and anteriorly These loops are altered in configuration in cases of mitral stenosis with left atrial enlargement and in cor pulmonale with right atrial enlargement[145] (p 122)

Derivation of Electrocardiographic Leads from the Vectorcardiogram

Theoretically it should be possible to derive the various leads of the electrocardiogram from the spatial vectorcardiogram or its plane projections Occasionally such derived electrocardiograms are essentially identical with those actually recorded by electrocardiography and they are termed concordant But often there are significant discrepancies and the derived and actual electrocardiograms are termed discordant These discrepancies are due to the imperfections in the vectorcardiographic method already enumerated notably the heterogeneity of the conducting medium particularly in relation to electrode placement, the inequality of distances between various electrode sites and the electrical center of the heart a possible continuous change in the electrical center the insufficient remoteness of some of the electrode positions and the eccentric position of the heart in the reference frame[11, 19, 109, 153, 17]

Discordance is particularly frequent in the precordial leads especially in extremely vertical or extremely horizontal hearts Milnor et al[126] emphasized their finding that conventional precordial leads do not usually lie in the same transverse plane as the nullpoint

(electrical zero) as an important factor in accounting for discrepancies between the precordial electrocardiogram and that derived from the horizontal plane vectorcardiogram The problem of adequate electrical remoteness of the electrode from the heart applies particularly to the precordial leads which are regarded by many as semidirect leads i e they are sufficiently close to the heart to be influenced predominantly by specific local areas in the cardiac electrical field which are in subjacent proximity to the electrode [150, 102] This belief is supported by the common clinical observation that the precordial leads may disclose more or less localized areas of anterior myocardial infarction not revealed by leads from more distant electrode sites (But see Duchosal et al [110, 109] and Milnor et al [136]) The theoretical basis of the vectorcardiogram and the claim that electrocardiographic leads may be accurately derived from the vectorcardiogram presuppose that the electrode sites including those for precordial leads are equally and adequately remote from the heart contentions which have not been conclusively demonstrated Nevertheless the discordance between actual and derived electrocardiographic leads may involve only quantitative discrepancies which often do not impair the practical value of the information obtained

The electrocardiogram may be derived from the vectorcardiogram by superimposing the various plane projections of the vectorcardiogram on an axial reference system representing the electrocardiographic leads or more directly by inspection The frontal plane vectorcardiogram is used to obtain the unipolar or standard limb leads the horizontal plane projection to obtain the unipolar precordial leads and if desired the sagittal plane projection to obtain esophageal or intracardiac leads [110, 141] Milnor and associates[136] described a panoramic vectorcardiograph' which not only permits the observer to obtain any desired view of the spatial vectorcardiogram on a cathode ray oscilloscope by adjusting two controls but which also derives and presents scalar electrocardiograms representing projections of the vectorcardiogram on any single lead axis

The frontal plane vectorcardiogram may be superimposed on the triaxial reference system of Bayley in such a manner that the point of intersection of the lead axes coincides with the origin or zero point of the vector loop (Fig 23) The horizontal axis denoting −180° on the right (observer s left) of the zero point and 0° on the left of the zero point represents the bipolar lead I the oblique axis running from +60° below to −120° above represents the bipolar lead II and the oblique axis from +120° below to −60° above represents bipolar lead III Midway between each pair of these three axes are drawn three other axes that from −150° above to +30° below, representing the aVR axis from −30° above to +150° below the aVL axis and from −90° above to +90 below the aVF axis A series of successive points are noted on the QRS loop in the order of inscription starting from and ending on the zero point The projection (perpendicular) of each of these points onto each lead axis discloses the polarity and magnitude of the electrocardiogram at corresponding moments in the cardiac cycle The *lead I axis is positive to the left (observer s right) of the vertical axis* leads II and III are positive below and negative above the horizontal axis leads aVR and aVL are positive above while aVF is positive below the horizontal axis The electrocardiogram at successive points (instants) of the vector loop is upright in any given lead if its projection falls on the positive and downward if its projection falls on the negative side of the lead axis The voltage at that point (instant) is indicated by the magnitude of the lead axis where the projection falls The same method may be used to outline the T and P as well as the QRS waves from their corresponding vector loops

In the normal frontal plane vectorcardiogram (Fig 21) the initial inscription often proceeds slightly to the right and its projection is on the right or negative portion of the lead I axis therefore a downward or Q wave is inscribed in lead I of the electrocardiogram Its magnitude is small because the distance from zero to the intersection of the axes is small Later the vectors of the loop are perpendicular to the lead I axis and there is neither a positive nor a negative deflection, in other words there is an isoelectric interval As the major portion of the loop then proceeds to the left, its successive points are projected onto the positive portion of the lead I axis and an upright or R wave is inscribed If the loop near its terminus again crosses the negative portion of the lead I axis a short distance from

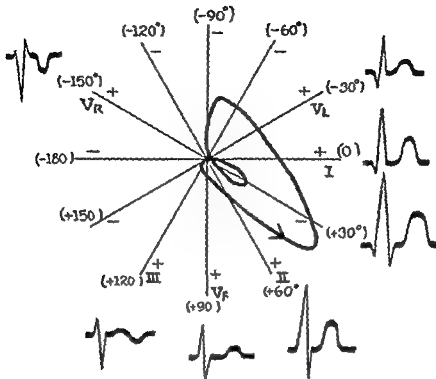

Fig 23 Standard bipolar and unipolar limb leads corresponding to and derived from frontal plane vector cardiogram superimposed on Bayley's triaxial reference system

zero a small S wave follows the R Since usually only a small initial portion of the loop is above the horizontal there is only a small Q wave in leads II III or aVF The major portion of the QRS loop being below the horizontal, it is projected onto the positive portion of leads II III and aVF, therefore the major deflection is upright in these leads i e an R wave follows the Q and is of greater magnitude If the terminal portion of the QRS loop is above the horizontal an S wave may also be inscribed in these leads If the vector at any point of the loop is perpendicular to a given lead axis its projection on the given axis at that instant is at the zero point and there is no electrocardiographic deflection i e it is isoelectric

The precordial leads may be similarly derived by superimposing the horizontal plane projection of the vectorcardiogram on an axial reference system representing the cross section of the thorax The origin of the loop coincides with the intersection of the axes and is placed either in the center or slightly to the left of center of the cross section The axes of the various precordial leads are then drawn from the center to the circumference corresponding to the site of placement of the precordial leads on the chest wall The projection of successive points of the loops on the various precordial leads is then determined (Fig 24)

The S T Vector and Segment

When the QRS loop is closed as it is normally the S T segment is isoelectric Just prior to ventricular depolarization the muscle surface is entirely positively charged and there is no potential difference Therefore the vectorcardiographic beam is at zero at the onset of the QRS loop and the electrocardiogram is at the isoelectric line Similarly, when there is complete depolarization the entire ventricular surface is negatively charged and there are no potential differences At this moment the QRS vector loop has reached its termination which is at the same zero point as the origin and the loop is closed Correspondingly the S T segment during complete depolarization represents no potential difference and is on the isoelectric line

When the QRS vector loop is open the S-T segment is above the isoelectric line in a given electrocardiographic lead when the open end of the loop is on the positive side of that lead axis the S T segment is depressed below the

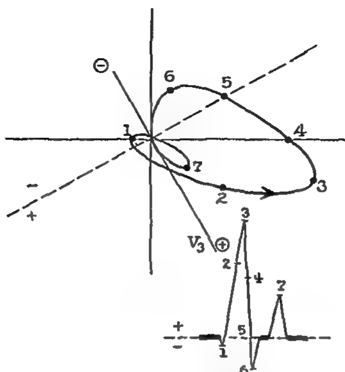

Fig 24 Derivation of a precordial unipolar lead V_3 from horizontal plane projection of vector loops QRS and T loops superimposed on rectangular coordinates with center (origin) of loop on zero point of coordinates Axis of derivation of V_3 drawn through origin of QRS loop Another line is drawn through origin perpendicular to this axis of V_3 Numbers indicate corresponding points on electrocardiogram and vectorcardiogram Amplitude of electrocardiogram deflections determined by size of projection onto V_3 axis Polarity determined by position below or above (left or right) interrupted line

isoelectric line when the open end of the loop is on the negative side of the given lead axis The distance between the point of origin and point of termination of the *open* QRS loop indicates the magnitude of the S T vector and the direction toward the terminus indicates the direction of the vector The S T segment is elevated if the vector is directed toward and it is depressed if the vector is directed away from the recording (positive) electrode, i e, the positive end of the lead axis

CLINICAL APPLICATIONS OF VECTORCARDIOGRAPHY

The clinical usefulness of the oscilloscope vectorcardiograph is as yet hampered by its costliness its cumbersome size and the necessary skill required in its use Furthermore extensive studies are still needed to correlate pathologic with vectorcardiographic findings The spatial vectorcardiogram is said to possess the advantage of presenting a unitary concept of the electrical field around the heart and of disclosing in a single curve all the findings in any electrocardiographic lead from any point or points of the body's surface whereas information by conventional electrocardiography is limited by the number of leads employed and by the position of the electrodes On the other hand it has been claimed that localized changes in the myocardium may not significantly affect the vectorcardiogram yet may be clearly disclosed in one of the precordial unipolar leads, which is in sufficient proximity to be modified by the subjacent myocardial change

Certain specific advantages in clinical practice have also been claimed for the vectorcardiogram over the conventional electrocardiogram More distinctive patterns of left and right ventricular hypertrophy have been disclosed by the vectorcardiogram and their identification is possible even in the presence of left or right bundle branch block Right ventricular hypertrophy may be more readily distinguished from right bundle branch block Patterns of myocardial infarction may sometimes be more distinctive in the vectorcardiogram than in the electrocardiogram

The pattern of acute myocardial infarction which is often obscured by bundle branch block in the electrocardiogram presents a distinctive pattern in the vectorcardiogram despite concomitant bundle branch block. These claimed specific advantages require further substantiation. For the present, vectorcardiography must still be regarded as a research technique.

VENTRICULAR GRADIENT[18, 81, 9, 100]

If the ventricular myocardium were absolutely homogeneous with respect to its metabolic processes and the generation of electromotive forces and if in consequence there was a uniform course, speed and duration of depolarization and an identical course, speed and duration of repolarization, the T wave would have the same voltage and duration as the QRS complex but would be oppositely directed (negative) and the areas under the QRS complex and under the T wave would add to zero. If the above conditions obtained except that the process of repolarization required more time than that of depolarization, the T wave would be oppositely directed to the QRS, their areas would be equal but the voltage of the T wave would be lower and its width (duration) longer than that of the QRS. Actually repolarization is slower than depolarization in the human heart, and the T wave is lower and wider than the QRS. But in addition, there are differences in ventricular metabolic and electrical activity, in consequence of which there are differences in the duration of depolarization in various regions of the ventricles. Repolarization occurs in some (subepicardial) portions *of the ventricle, while in other (subendo-*cardial) areas depolarization is not yet complete. These net differences in ventricular electrical activity of varying duration are termed the "ventricular gradient." Ventricular gradient has also been defined as "differences in the time course of the process of depolarization and repolarization representing mean deviation in the uniformity of the process of depolarization and repolarization," and also as "mean difference in duration of the excited state and net electrical effect of the differences in time course of the processes of depolarization and repolarization."

Since the course of depolarization is from the endocardial to the epicardial surface and since the subendocardial region remains depolarized longer than the epicardial regions, the effect of the ventricular gradient on the conventional electrocardiogram is to add a positive potential difference to the T wave which would otherwise have been negative if the duration of depolarization had been uniform throughout the ventricular muscle. The ventricular gradient converts the expected negative T wave into a positive one in almost all leads of the conventional electrocardiogram, except in those taken from some sites overlying the right ventricle or posterior aspect of the base of the left ventricle.

Since, omitting the effect of the ventricular gradient, the area of the T wave is equal to the area of the QRS but of opposite sign, any increase in the positive area of the QRS (e.g., due to ventricular hypertrophy, premature beats or bundle branch block) results in an equal increase in the negative area of the T wave, i.e., in its depth, duration or both. If the increase in T negativity is great enough it may more than neutralize the normal positive gradient and result in a negative T wave. Such negative T waves which are secondary to changes in the height or duration of the QRS (which in turn are due to alterations in the course of depolarization) are termed *secondary T wave changes*. If, however, there are fundamental metabolic changes in the muscle as a result of changes in blood supply or other injuries, there are alterations in the differences of duration and intensity of depolarization and the course of repolarization, i.e., the ventricular gradient is altered. If this is less positive than the normal, the T wave may be low or negative. Such a *negative T wave due to altered course of repolari*zation and not to alteration in depolarization (QRS) is termed a primary T wave change. Determination of the ventricular gradient reveals whether T wave alterations in the electrocardiogram are primary (gradient abnormal) or secondary (gradient normal).

The ventricular gradient may be represented as a spatial vector $s\hat{G}$, while its projection on a frontal plane is often represented by the vector $\hat{G}$.[100] The direction of the vector is from the area in which the mean duration of the excited state is greatest to the area in which it is least. Normally this is from the subendocardial to the subepicardial region. Unlike the conventional vectorcardiogram the ventricular gradient stresses the factor of

time, i e, duration of electrical potential differences as well as their intensity The ventricular gradient can be determined from the areas of the QRS and T waves since the vector of the ventricular gradient is equal to the sum of the vectors representing the QRS and T wave areas This can be determined by the parallelogram law The areas of the QRS and T waves in leads I and III are measured in microvolt seconds each square of the electrocardiograph paper representing 0 04 microvolt second or 1 unit when the paper runs at its conventional speed of 25 mm per second These areas represent the mean electrical force of depolarization

The area QRS_2 = area QRS_1 + area QRS_3 in simultaneous curves just as by Einthoven's theory $R_2 = R_1 + R_3$ If the areas of QRS of any two leads are plotted as microvolt seconds on the sides of the Einthoven triangle or in the triaxial reference system a vector is obtained $\hat{A}_{QRS}$ which represents the mean electrical axis ' during the entire period of the QRS (See p 35) Similarly by plotting the areas of the T waves in two leads, a vector $\hat{A}_T$ is obtained for the mean electrical axis throughout the entire period of T The mean ventricular gradient $\hat{G}$ (frontal plane projection) is obtained on the same triaxial reference diagram as the resultant of $\hat{A}_{QRS}$ and $\hat{A}_T$ by the law of the parallelogram of vector forces The value of determining the frontal plane ventricular gradient has been questioned[144] To obtain the spatial ventricular gradient $s\hat{G}$, it would be necessary to determine similarly the gradient projection on at least two planes among the frontal horizontal and sagittal Ivancic and Mikulicic[126] have described a method for determining and calculating the spatial ventricular gradient with the aid of anteroposterior horizontal and vertical bipolar transthoracic leads

An integrating circuit for the measurement of the areas of the waves has been devised[127, 96] It is probable that the cathode ray oscilloscope will replace the cumbersome manual derivation of the gradient vector as it has replaced manual derivation of the vectorcardiogram Perhaps then it will be possible to determine whether the ventricular gradient has any significant clinical application Thus far studies have been made of the positional relationship of the ventricular gradient $\hat{G}$ (or $\hat{A}_{QRST}$) to the vector of the QRS, $\hat{A}_{QRS}$ and to the anatomic position of the heart, and to determine whether T wave changes are due to primary myocardial disease[143]

Chapter 3

BALLISTOCARDIOGRAPHY, PHONOCARDIOGRAPHY, CARDIAC CATHETERIZATION AND OTHER GRAPHIC METHODS

BALLISTOCARDIOGRAPHY

Ballistocardiography is a technique of graphic representation of the movements of the body imparted by the ballistic forces (recoil and impact) associated with cardiac contraction and ejection of blood and with the deceleration of blood flow through the large blood vessels[4, 6, 24, 8, 27] These movements quantitatively very minute are translated by a pickup device into an electrical potential which is suitably amplified and recorded on a conventional electrocardiograph machine During the recording the body must be completely at rest and relaxed in order to minimize bodily movements due to any other cause i e muscular contraction The ballistocardiogram should be taken with the patient as close as possible to the basal state at least an hour after smoking and in the absence of the recent administration of such drugs as Benzedrine It is usually recorded during quiet respiration but should also be taken during deep inspiration with the mouth open during full expiration and after mild exercise If direct body ballistocardiographs are used the patient must lie on a non elastic surface free of vibrations with a wooden block or sandbag supporting the heel at the Achilles tendon and a pillow under his head[29, 4] Other methods have been devised to minimize distortions due to the platform or surface on which the patient lies (infra)

The ballistic force which imparts movement to the body is a spatial vector which varies in magnitude and in direction in space throughout the cardiac cycle[29] Most of the ballistocardiographic techniques have recorded those forces which are exerted in the longitudinal axis of the body i e in the headward or footward direction Thus they record the projection of the instantaneous spatial vector along the longitudinal axis of the body But ballistocardiograms may be obtained of bodily movements due to force acting in a lateral direction or in various spatial directions and the ballistic motion in three directions may be simultaneously recorded[19, 22, 24, 25, 31] Dock[16] employed a spring opposed platform (65 by 55 cm with free side-to-side motion, contained in a frame which moved freely from front to back The thorax of the prone or supine subject was positioned on the platform so that lateral and dorso-ventral ballistocardiograms were obtained from the thorax alone Head foot ballistocardiograms were simultaneously obtained by an electromagnetic shin pickup These three dimensional techniques may better disclose certain information regarding blood flow than the conventional longitudinal ballistocardiograms

BALLISTOCARDIOGRAPH MACHINES

Two types of ballistocardiographic apparatus are generally employed (1) the type in which the patient is on a moving table and (2) the direct body type in which the apparatus rests on the patient's body, usually on the shins

Most of the pioneer observations were made with the high frequency, undamped ballistocardiograph of Starr,[52] which consisted of a hard movable table top supported by short strips of flat steel spring The subject lies supine on the table, to which are transmitted the impacts and recoils arising from cardiac contraction and the flow of blood The natural frequency of this table was about [illegible] cycles per second, which not only damped or eliminated the low frequency waves generated in the heart and great vessels, but also caused

amplitude distortion with respect to frequency, phase displacement and differentiating effects.[33]

Nickerson and Curtis[36] introduced a critically damped, low frequency table with a natural frequency of about 1.5 cycles per second. This, too, tends to cause phase and duration distortion of the ballistocardiographic waves and amplitude distortion with respect to frequency. Consequently there is a reduction in amplitude and increase in duration of the ballistocardiographic waves. High frequency components are not registered. Respiratory waves which are of low frequency, are well transmitted by this table and recorded on the ballistocardiogram causing a wavy baseline which distorts the record. Consequently it is desirable to suspend respiration during registration of the ballistocardiogram. The important effects of expiration and inspiration on the ballistocardiogram cannot be studied with this table.

The apparatus of both the Starr and Nickerson types is cumbersome, costly, not portable and therefore not generally available. Ballistocardiography has become a practical clinical procedure only since the availability of a simple portable and inexpensive apparatus introduced by Dock and Taubman.[18] By their method or modifications thereof, the patient lies supine on a fixed table or floor and a crossbar is placed across the shins. The impacts and recoils imposed on the body by cardiac contraction and the expulsion and flow of blood in the large vessels are translated into movements of the bar and thence into electrical potential by means of a photoelectric cell or electromagnet. But body frequency and damping cause distortions in the ballistocardiogram, which should be borne in mind when it is applied to physiologic or clinical studies.[56]

The artefacts and distortions of the ballistocardiographic tracing introduced by oscillations created by the body and its contact with a table or platform, not related to cardiovascular dynamics, have recently been critically reviewed by Talbot and Harrison.[54] To minimize these distortions Von Wittern[61] used a light suspended platform (pendular bed) of very low natural frequency, Talbot et al.[53, 15] placed the subject on a very light table floating in a pool of mercury (aperiodic ballistocardiograph), and Tobin et al.[59] devised an electrical method of filtering out body resonance distortions. Rappaport[35a] employed a bed weighing only 4 lbs. and with a natural frequency of less than 0.3 oscillations per second in order to minimize restraint of free body movement and to eliminate extraneous distortions of the ballistocardiogram.

PICKUP DEVICES

A great variety of pickup devices may be employed to obtain ballistocardiograms. They record either (a) the distance of body displacement, or (b) its velocity or (c) its acceleration caused by cardiac ballistic forces.

Photoelectric Device

The photoelectric device records displacement due to body motion, the latter causing movements of the crossbar which modifies the amount of light falling on a photoelectric cell either by passing between the light source and cell or by affecting a hinge which regulates the light. The photoelectric cell device is connected to the right and left arm cable terminals of an electrocardiograph machine and the ballistocardiogram is recorded with the switch selector on stardard lead I. Because of wide respiratory undulations of the photoelectric ballistocardiogram, an electrical filter is incorporated in the apparatus to reduce these swings.

Electromagnetic Pickup Device

The electromagnetic pickup device consists of an Alnico magnet producing a magnetic field and a coil of wire within the magnetic field, so arranged that magnetic lines of force are cut by motion of either the wire coil or the magnet transmitted through contact with the crossbar on the shins of the subject. These changes in magnetic lines of force result in electrical energy of varying potential which is transmitted through the coil of wire, the ends of which are hooked up to the electrocardiograph machine as described above. The electrical current generated is proportional to the *velocity* with which magnetic lines of force are cut. Thus this device records velocity of body motion, not the degree of displacement. Actually the unmodified electromagnetic device is too sensitive, and results in artefacts caused by even the slightest body tremor. It tends to exaggerate the high frequency ballistocardiographic waves. Consequently, condensers of 20 to 50 microfarads are usually inserted across the wire coils,[17] which tend to eliminate these distortions, but the resulting curves are altered so as to resemble the dis

placement records obtained with the photo electric cell If only a 2 microfarad condenser is inserted most of the oscillations due to muscle tremor are eliminated with retention of the velocity type of curve

Accurate timing of the ballistocardiographic waves may be obtained with 2 channeled electrocardiographs by taking a simultaneous electrocardiogram, phonocardiogram or radial pulse tracing With single-channeled machines timing is accomplished by attaching the electrocardiograph in series with the limb electrodes [22, 1] The electrodes are applied as for an electrocardiogram The left leg lead is detached from the left leg electrode and connected with the left arm terminal of the ballistocardiograph The detached left leg electrode is now connected with the right arm terminal of the ballistocardiograph The tracing is then recorded on lead II or lead III whichever has the taller RS complex

With either the photoelectric or electromagnetic device, the electrocardiographic sensitivity is set to give 1 cm deflection per millivolt and the pickup device has a sensitivity which results in maximum ballistocardiographic deflections of 2 to 3 cm in the normal young adult For more exact quantitative standardization a known force is imposed on the body (e g by striking the shoulder with a pendulum transmitting a known force) and the resulting deflection on the record is measured [18, 40, 48]

Acceleration Ballistocardiogram

For most accurate quantitative analysis of the ballistocardiographic waves a pickup dependent on the acceleration of body motion rather than on displacement or velocity is required For it is acceleration not displacement or velocity which is a measure of the force of motion imparted by the recoil of the heart and the impacts of blood ejected from the heart along the vascular system Acceleration ballistocardiograms have been obtained by apparatuses which electronically differentiate the velocity ballistocardiogram obtained with the electromagnetic pickup and thereby convert it into an acceleration ballistocardiogram [46, 9]

Elliot and associates [9] have developed an ingenious device for obtaining a direct acceleration ballistocardiogram The pickup or accelerometer operates on electrokinetic principles whereby electrical changes occur at the surfaces of contact of a mercury sulfuric acid interface (the so-called U effect) The pickup element is actually a capillary tube with alternate layers of mercury and normal sulfuric acid At each end of the capillary tube is a mercury seal into which a copper or platinum electrode is inserted Upon motion of the element, changes in electrical voltage are induced by changes in the mercury acid interfaces which are proportional to the change in contour of the interfaces and these in turn are proportional to the acceleration of imparted motion This accelerometer is readily calibrated for quantitative study of the ballistocardiographic waves by use of a simple pendulum Once calibrated its response can be standardized by use of the 1 millivolt standardization of the recording electrocardiograph The apparatus is simple and portable and is applied to the shins as is the Dock electromagnetic device

THE NORMAL BALLISTOCARDIOGRAM [6, 17, 21, 43, 4, 12, 41, 48]

The normal ballistocardiogram (BCG) consists essentially of a series of consecutive waves, termed H, I, J K L M N O etc, forming a distinctive pattern (Fig 25) The upward waves H J L N represent headward impacts or recoils of the body whereas the downward waves I K M, O represent footward movements The waves H through K occurring during systole are the most prominent and important The waves L to O are diastolic in time and of much smaller amplitude Corresponding waves occur in the lateral and dorsoventral ballistocardiograms [16, 34]

Atrial Ballistocardiographic Complex

Preceding the H wave is a group of smaller waves associated with the ballistic effects of atrial systole namely D E F G also termed atrial h i j, k These are alternately headward and footward waves respectively the D or h wave being due to recoil from atrial systole and E or i due to impact of filling of the ventricle Since the D wave reaches its peak at about 0 10 second and the E wave at about 0 25 second after the onset of the P wave of the electrocardiogram and the F and G waves may last up to 0 40 to 0 50 second after the onset of P it is apparent that most of the D E F G complex overlaps the systolic complex of the ballistocardiogram which begins 0 16 to 0 28 second after the onset of P Therefore the atrial ballistocardiographic waves may significantly modify the

II and I waves, increasing or decreasing their amplitude

Ventricular Systolic Complex

H is a small upward wave beginning 0 04 to 0 08 second after the electrocardiographic Q wave and lasting 0 05 to 0 07 second It coincides with isometric contraction[29] and may be due to headward motion of the atrioventricular septum and of the blood in the atria as the atrioventricular valves are tensed and moved toward the atria It may be due in part also to superimposition of the atrial J wave (J') It is improbable that it is due to atrial contraction because the H wave often persists during atrial fibrillation [14] Increased prominence of the H wave may be observed with myocardial disease and heart failure and in cases of hypertension

The I is a deep downward wave and the J a prominent upward wave which occur together during ventricular ejection The I wave is produced by the footward recoil of the body to the early systolic ventricular ejection of blood into the aorta and pulmonary artery By correlation with the electrokymogram the I wave appears to coincide with the beginning of the rise of the aortic wave The J wave is usually the most prominent wave of the ballistocardiogram and is caused by the headward impact of blood at the arch of the aorta and bifurcation of the main pulmonary artery In abnormal cardiac states the I wave may not be evident or it may be decreased in amplitude Similarly the J wave may be diminished in amplitude, slurred and notched, and its peak may be delayed to 0 28 second or more beyond the onset of the QRS, whereas normally the peak of the J occurs 0 22 to 0 26 second after onset of the Q wave

The K wave directed footward the last deflection of the systolic complex, occurs just prior to the second heart sound and is attributed to deceleration of blood flow in the aorta The aortic after fling and the impact of the blood on the smaller arteries also contribute to this wave It extends downward to the level of or slightly below the depth of the I wave The K wave is best recorded by the electromagnetic ballistocardiograph and varies with the type of instrument used Since slowing of the blood flow in the descending aorta by the peripheral resistance is largely responsible for the K wave its amplitude is greater and its slope steeper when the peripheral resistance is increased as in essential hypertension or when there is arterial inelasticity, as in arteriosclerosis of the aorta associated with aging The K wave is also deepened by increased flow in the descending aorta when the cardiac output is augmented by digestion exercise or pregnancy and it is decreased with diminished cardiac output in shock When there is shortening or obstruction of the aorta the K wave is small or absent as in aortic thrombosis or in coarctation of the aorta [7, 37]

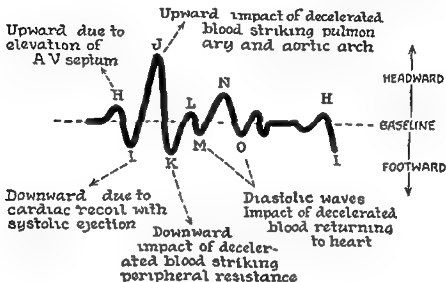

Fig 25 Diagram of ballistocardiographic waves and their origin

The I, M, N and other waves occur in diastole and are normally much less prominent than the systolic waves In three dimensional ballistocardiograms the waves following K are predominantly longitudinal suggesting that they are derived from forces directed along the aortic (longitudinal axis)[34] They may become quite prominent and even exceed the I and J waves in amplitude in conditions such as constrictive pericarditis heart failure or during the Valsalva experiment According to Tannenbaum et al[35] the L wave is part of the systolic complex since the nadir of the L wave corresponds to the dicrotic notch in the aortic and pulmonary artery electrokymograms The L wave is a headward deflection occurring during isometric relaxation of the ventricles and is presumed to be due to impact on the atrioventricular valves which are forced upward toward the atria

The M wave occurs during the early diastolic influx of blood into the ventricles and is a footward deflection due to the impact of blood impinging on the apex

The N wave is a headward deflection at the end of the early diastolic filling of the ventricles With arrest of the inflow as ventricular pressure rises there is a reflux toward the atrium and consequently the headward N wave

Effect of Respiration on the Ballistocardiogram

Marked variations in amplitude of the waves of the ballistocardiogram particularly of the I and J ejection waves occur during the phases of respiration[13] Normally the amplitude of the inspiratory I-J stroke was found to be less than twice that of the expiratory I J stroke in the electromagnetic ballistocardiogram[1] The waves increase in size with the onset of inspiration and diminish during expiration These phasic variations are more striking in older subjects than in young adults and also become exaggerated in the presence of cardiac disease The effect of respiration is attributed to its influence on the filling of the right ventricle and consequent right ventricular ejection

Thus the increase in amplitude of the I J waves during inspiration reflects essentially right ventricular activity Similarly during expiration reduction in amplitude of the I and J waves is related to a diminished contribution of the right ventricle to the ejection waves Therefore, abnormalities in left ventricular ejection may be observed best or only during expiration when the right ventricular component is minimized The Valsalva maneuver by interfering with venous return to the right ventricle and thereby diminishing its stroke output similarly magnifies the left ventricular component of the ballistocardiogram and its abnormalities of ejection as disclosed in the I and J waves The ballistocardiographic waves are diminished in amplitude during the Valsalva maneuver because of the reduction or loss of the right ventricular contribution

Studies of three-dimensional ballistocardiograms may alter or extend our concepts of the influence of respiration The *lateral* systolic IJ wave *increases* in size during expiration whereas the IJ decreases in amplitude with expiration in the *head foot* and *dorsoventral* ballistocardiograms[34] The increase in lateral IJ during expiration has been related to a rise in the diaphragm and apex of the heart with a change in the axis of left ventricular ejection

Effect of Exercise

Mild exercise increases the amplitude of the HIJK complexes in the normal subject without altering their configuration[33] But abnormalities do appear with increasing frequency after the fifth decade Exercise has been said to increase the incidence of ballistocardiographic abnormalities in patients with coronary artery disease or diminished cardiac reserve Occasionally abnormalities present in the basal ballistocardiogram may disappear immediately after exercise Tall L waves may be present briefly after strenuous exercise[17]

Effect of Aging

Progressive increase in age is associated with increasing frequency of abnormal ballistocardiograms in subjects who are presumed to be free of cardiovascular disease Beyond the age of 45 more than one third of apparently normal men and one fifth of apparently normal women have an abnormal ballistocardiogram beyond the age of 60 more than half of persons without apparent heart disease have abnormal ballistocardiograms[2] It is uncertain to what extent such abnormalities actually denote cardiovascular abnormalities which are not otherwise demonstrable

With increased age the I wave diminishes in height from about 5 mm at the age of 20 to 2 5 mm at the age of 60 while concomitantly

the J wave decreases in amplitude from about 8.5 to 5.5 mm. Consequently the ratio of the H and K waves to the I and J waves respectively is significantly increased.[50] Since many of the ballistocardiographic changes observed with aging are similar to those observed in cases of clinical coronary heart disease, it was suggested that the ballistocardiographic abnormalities associated with aging may actually be indicative of the increasing frequency of coronary atherosclerosis with age. On the other hand, studies with three-dimensional ballistocardiography have shown that with aging the lateral systolic IJ wave increases in amplitude while the head-foot IJ diminishes.[34] This is due to a more transverse axis of ejection because of the tortuosity and elongation of the aorta in older individuals.[18] Changes in the position of the heart and velocity of ejection may also be concerned with the large lateral IJ wave. Thus a diagnosis of an abnormal ballistocardiogram based only on a diminished head-foot IJ in older subjects is unjustified. An abnormal head-foot ballistocardiogram is more likely to denote cardiac disease in the younger adult than in the older subject.

Alterations in the ballistocardiogram have been described after smoking,[9, 25, 30] and digestion and in a variety of noncardiac conditions including obesity, orthopedic abnormalities, pulmonary disease, nervous states, parkinsonism, fever, hyperthyroidism, anemia and adrenal disease and as a result of technical factors.

THE ABNORMAL BALLISTOCARDIOGRAM

Abnormalities in the ballistocardiogram are characterized either by aberration in the appearance of the general pattern, by disturbance in the regularity of the sequence of normal waves, by changes in the absolute or relative size of the individual waves, or by several of these (Fig. 26). Changes involve essentially or exclusively (1) the systolic I-J-K complex in all beats or only during expiration, or (2) the H wave or the diastolic waves, or (3) there may be an exaggeration of the respiratory variation of the amplitude of the I-J deflections.

Classification of abnormal ballistocardiograms may be based on the criteria suggested by Brown and associates.[8]

Grade 1. Regularity and distinctiveness of pattern are preserved and inspiratory IJ

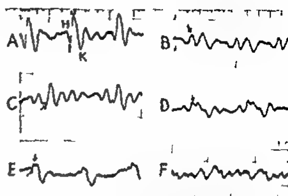

Fig. 26. Variations of abnormal patterns. *A*, Normal. *B*, Prominent H wave. *C*, Diminished I wave. *D*, Notched J wave. *E*, Small I wave and low notched J wave. *F*, Bizarre pattern. (Courtesy Dr. R. Taymor.)

amplitude is normal. The expiratory complexes vary, some showing diminished amplitude and loss of distinctiveness of the individual waves.

Grade 2. One half or more of the complexes are abnormal, chiefly during expiration, but the inspiratory complexes may also be diminished in amplitude. The J wave may be notched; I or K absent.

Grade 3. The amplitude is low in all complexes. Most of the complexes are abnormal both in expiration and inspiration with respect to regularity and definitive pattern but they are individually identifiable.

Grade 4. Totally abnormal complexes are present throughout. The complexes are all of low amplitude and unidentifiable. Grade 1 denotes minimal abnormality and may be due to extracardiac factors modifying the venous return or change in anatomic axis. The other grades indicate increasing degrees of abnormality.

Inspection of the ballistocardiographic record may disclose an exaggeration of the normal respiratory variations in amplitude of the I-J waves. A reduction of the expiratory amplitude to less than half of the inspiratory amplitude is abnormal and may be observed in older individuals and as a result of extracardiac factors, especially pulmonary emphysema or fibrosis. It is also observed in many patients with hypertension. When the majority of I-J deflections are thus abnormally small in expiration (Grade 2), and especially when these amplitude changes are associated with abnormal or bizarre patterns in expiration (Grade 3), the changes are prob-

ably associated with myocardial dysfunction But in older individuals whose ballistocardiograms are not bizarre in form, three-dimensional ballistocardiograms may show that the lateral IJ complexes are not small and do not decrease or even increase in expiration March[34] suggested that the tracing may be considered normal in the absence of bizarre complexes if the ratio

$$\frac{(IJ_{\text{Head foot}} + IJ_{\text{lateral}}) \text{ in expiration}}{(IJ_{\text{Head foot}} + IJ_{\text{lateral}}) \text{ in inspiration}} \times 100$$

is over 60

The amplitude of the systolic complex may be unusually high in patients with high cardiac output owing to such conditions as hyperthyroidism anemia and arteriovenous fistula even in the absence of cardiac disease The high amplitude persists in the high output heart failure associated with these diseases Low amplitude of the e waves may be observed in cases of severe myocardial disease shock myxedema adrenal and pituitary insufficiency but also in the absence of organic disease

Abnormalities of I J Complex (Fig 26 C F)

The I J complex especially the I may be decreased in amplitude absolutely and relative to the amplitude of the K wave The I wave may be slurred its peak blunted or notched, or it may be completely absent or obscured Similarly the J wave may be slurred or notched or its peak may be delayed Deep notching of the J wave may produce an M shaped pattern late in systole Notching of the J wave may be associated with a high take-off from the H wave I either being absent or appearing as a small notch These abnormalities may appear only and should therefore be sought in full expiration and the ballistocardiogram in expiration should be contrasted with that in deep inspiration

Abnormalities in the K Wave

Abnormality of the K wave may be characterized by increased depth and an early trough as in essential hypertension and aortic arteriosclerosis The deep K wave may then dominate the ballistocardiogram in contrast with the lesser amplitude of the I J waves

The K wave may be shallow or absent (cut off) in cases of coarctation of the aorta or aortic thrombosis with obstruction It is also decreased in shock The type of ballistocardiograph used must be considered in evaluating the amplitude of the K wave since the latter is deeper with the high frequency than the low frequency table, with direct body apparatus than with the table types and with the electromagnetic pickup than with the photoelectric

Abnormalities in the H Wave

The H wave may be greatly increased in height (Fig 26B), which may equal or exceed that of the J wave H and J waves of equal height separated by a notch, are common in coronary artery disease but occur also in cases of mitral stenosis hypertension heart failure and constrictive pericarditis Such complexes are described as fused H-J or 'M type' patterns They may become more evident or appear only during expiration

Duplication or splitting of the peak of the H wave may occur in cases of mitral stenosis with sinus rhythm or with atrial fibrillation Presumably rigidity of the mitral valve interferes during isometric contraction with the headward motion of the atrioventricular septum which is responsible for the H wave

Changes in the Diastolic Waves (L M N O)

Tall L waves are observed in a variety of diseases when these are complicated by heart failure They have also been noted in some cases of coronary disease of mitral stenosis, of myocarditis and after smoking

The L and M waves are often small and the headward N wave tall in cases of tight mitral stenosis, and in some cases of constrictive pericarditis[43] Tall N waves are often associated with L and M waves of high amplitude in cases of heart failure and protodiastolic gallop and in some cases of mitral insufficiency Deep O waves in the presence of tall L M and N waves may be observed with bradycardia in cases of high stroke output and atrial fibrillation and in aortic insufficiency

CLINICAL CORRELATIONS OF THE BALLISTOCARDIOGRAM

Although abnormal ballistocardiograms are found commonly in certain cardiovascular diseases, specific abnormal patterns cannot be attributed to localized anatomic lesions or specific etiologic diseases Abnormalities in the ballistocardiogram may denote abnormalities in systolic contraction and ejection of blood abnormalities in the propulsion of blood through the great vessels alterations in the position of the heart and axis of ejection of blood vascular changes resulting in abnormal response to the impact of blood masses, as well as abnormalities in transmission of these im

pacts and recoils through the body tissues and the ballistocardiographic apparatus. On the other hand, it must also be emphasized that the ballistocardiogram may be normal in patients with organic heart disease as in compensated rheumatic cardiovalvular disease after compensation has been restored to the failing heart, and occasionally in patients with angina pectoris or after acute myocardial infarction.[21]

Coronary Artery Disease, Angina Pectoris Myocardial Infarction[5, 11, 27, 3] **(Fig 27)**

Abnormal ballistocardiograms have been observed in over 90 per cent of patients with amplitude.[11] But even when the amplitude of the systolic waves is increased, normal wave pattern may not be restored. Although ballistocardiographic abnormalities are the rule in angina pectoris there is no characteristic pattern of angina pectoris or coronary artery disease, the changes observed do not differ significantly from those seen in patients with hypertension or various forms of myocardial disease.

Ballistocardiographic abnormalities are observed much more frequently than electrocardiographic changes in cases of angina pectoris without a history of myocardial infarction.

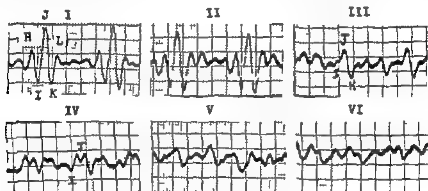

Fig 27 Ballistocardiograms in coronary heart disease
I Normal ballistocardiogram (BCG) in normal 41 year old white male
II Normal BCG in 64 year old man with history of acute myocardial infarction four years previously. Electrocardiogram shows evidence of old anterior wall infarction
III 69 year old man. Multiple acute myocardial infarctions. BCG shows very low amplitude of I wave
IV 69 year old man. Angina pectoris. Abnormal electrocardiogram. BCG shows low I wave and notching of J wave
V 67 year old man. Coronary heart disease. Blood pressure 190/100. BCG shows low I wave and poor definition of remaining waves
VI 50 year old male. Acute myocardial infarction one year previously. BCG shows bizarre pattern

angina pectoris at rest or following exercise. The abnormalities include increased respiratory variation in the I J deflections, low amplitude, notching or fusing of the H I-J complex or completely bizarre systolic complexes. The diastolic complexes show little or no change in the absence of heart failure. Abnormalities in angina pectoris may be present only in expiration or only after exercise or may be increased by these factors. Abnormal ballistocardiograms after smoking occur with much greater frequency in patients with coronary artery disease than in normal subjects.[11, 45, 30] Following the administration of nitroglycerin to patients with angina pectoris whose ballistocardiograms have been abnormal the low amplitude of H I J is increased, notched J waves may disappear, the I J stroke is lengthened, and L waves are reduced in amp-

farction. That these ballistocardiographic changes are significant appears to be suggested by follow up studies which disclose a surprisingly high incidence of subsequent coronary heart disease and mortality rate in subjects with abnormal ballistocardiograms who are otherwise apparently normal.[47, 10]

In cases of *myocardial infarction* the ballistocardiogram may be normal immediately after the acute attack or may show Grade 3 or 4 abnormality, including low amplitude of systolic waves, notching of J and fusion of H J. Very small or absent I waves, and small I with delayed J K segment, have been noted frequently. Even in those patients with normal tracings in the early period abnormalities almost always appear by the third to fifth week. Following the patient's recovery from acute myocardial infarction, his ballistocardio-

gram may revert to normal or show only Grade 1 changes or Grade 3 or 4 changes may persist[32] There is some evidence that the incidence of another myocardial infarction in a year or two or of sudden death is much higher in patients with asymptomatic healed myocardial infarction who ballistocardiograms show Grade 3 or Grade 4 changes than in those who ballistocardiograms are relatively normal[33] Thus abnormal ballistocardiograms in patients with coronary artery disease are regarded as being of value not only in suggesting or confirming the diagnosis of latent or clinical coronary artery disease but especially in prognosis[33, 50] But since hypertension which is frequently associated with an abnormal ballistocardiogram often accompanies coronary artery disease, an abnormal ballistocardiogram may have no diagnostic significance with respect to coronary artery disease in the presence of hypertension Similarly the ballistocardiogram may have little or no diagnostic value in coronary artery disease after the age of 45 because of the frequency of abnormal tracings after that age in apparently normal persons

Hypertension

The ballistocardiogram is normal in most cases of mild hypertension and in most hypertensive patients below the age of 25 When the tracing is abnormal it most often discloses an increased respiratory variation in the I J amplitude Brown's Grade 1 abnormality[33] Such abnormalities are usual in advanced or prolonged hypertension The K waves are usually deep in uncomplicated hypertension except when the hypertension is due to coarctation of the aorta The deep K waves are often associated with shortening of the I J stroke or absence of the I wave Sometimes the abnormalities observed in hypertension are due to associated coronary heart disease or heart failure Exercise may normalize an abnormal tracing or intensify the abnormalities, possibly distinguishing uncomplicated hypertension from that associated with myocardial disease or heart failure Conversion of an abnormal tracing to a normal one after the administration of hypotensive drugs[41] suggests that the ballistocardiographic abnormalities may actually be due to hypertension

Mitral Stenosis

There may be no abnormalities in well compensated cases Or there may be only a diminution in the respiratory variation of the amplitude of I-J More distinctive abnormalities have also been associated with mitral stenosis Davis et al[16] observed an abnormal late diastolic or early systolic footward wave in 13 of 14 patients with pure mitral stenosis This abnormal wave resembled the following footward I wave giving the appearance of a double I wave Occasionally it appeared as if there were a fusion of the waves resulting in a wide rounded I wave The abnormal footward wave in contrast with the normal footward C wave, occurred later than the latter and was associated with a late I wave Despite its consistent occurrence in mitral stenosis this wave is not diagnostically specific for it occurs also in constrictive pericarditis and in aortic or iliac thrombosis The occurrence of the abnormal wave in mitral stenosis was attributed to increased pulmonary vascular resistance right ventricular hypertrophy ventricular asynchrony or an abnormal left atrial ventricular gradient

Henderson[26] observed two abnormal waves in the ballistocardiograms of 100 patients with mitral stenosis (1) an RI footward deflection near the foot of the HI stroke occurring 0 06 to 0 1 second after the beginning of the QRS and (2) an RJ headward deflection immediately after RI and 0 08 to 0 12 second after the onset of the QRS complex of the electrocardiogram These abnormal waves were closely related to the onset of the right ventricular ejection

Mitral Insufficiency

When mitral insufficiency is severe the I wave may be diminished the peak of the J wave may be delayed and it may be slurred or notched A deep M and a tall L and N have been considered as most typical of severe mitral insufficiency but these are not specific These changes have been attributed to exaggerated rapid filling of the left ventricle and reflux in early diastole

Aortic Insufficiency

The I J stroke may be of high amplitude, partly because of augmented stroke volume, but chiefly because of greatly augmented speed of ejection in early systole The peak of the J wave occurs early e g in 0 20 second after onset instead of 0 22 to 0 26 second as occurs normally The K wave may show widening and notching probably due to altered flow in the aorta caused by the aortic reflux

Aortic Stenosis

When the stenosis is severe the I wave may be prominent and widened The widening may be due to delay in impact against the arch due to increased and protracted recoil from ventricular ejection of blood past the narrowed aortic orifice Van Lingen et al[60] described an angulation or bowing of the J-K segment with the low frequency ballistocardiogram With the high frequency apparatus they observed a small K and deep M

Congenital Heart Disease

Pulmonic stenosis may be associated with low amplitude systolic waves and diminution in respiratory variation in amplitude

Atrial and ventricular septal defects and *patent ductus arteriosus* usually show normal ballistocardiograms but the systolic complexes may be of high amplitude

Coarctation of the aorta is characterized by short (cut-off) K waves[7, 37]

Constrictive Pericarditis

There is a reduction in amplitude of the systolic complexes, sometimes associated with an absence of the I wave and notching of the J[65] The L and N waves may be large

Heart Failure

The ballistocardiogram shows abnormalities which may be due to the underlying disease such as coronary heart disease, namely diminution or disappearance of the I wave and decreased amplitude slurring notching and delayed peak of the J wave especially evident in expiration But in addition, in heart failure there are frequently large diastolic waves especially L and N, and there may be a prominent H wave These may be related to exaggerated impacts against the atrioventricular cusps during isometric contraction (H) and isometric relaxation (L), or exaggerated recoil from atrial ejection (N) due to the elevated pressure in the left atrium Low amplitude and distorted configuration of the systolic waves are common in heart failure of the low output type But in the forms of high output failure associated with hyperthyroidism, anemia and so on, the I J waves associated with ventricular ejection may be of high amplitude

CLINICAL EVALUATION

The relative simplicity low cost and ready availability of the portable ballistocardiograph have led to surprisingly rapid acceptance and widespread use of this device in everyday office practice before its physiologic basis has been established, before its clinical value has been clearly demonstrated and its possible field of value sharply defined There is more glibness than experimental basis in the proffered explanations of the mechanism responsible for ballistocardiographic abnormalities observed in various diseases The influence of the surface on which the patient lies, of the ballistocardiographic apparatus, and of extracardiac factors is either insufficiently understood or inadequately stressed The significance of ballistocardiograms which are abnormal when recorded in one direction, but normal in another, is undetermined

It appears that ballistocardiography provides a kind of information regarding cardiac function namely an index of the force of the heart and velocity of ejection, which is different from and may therefore supplement that offered by other graphic methods of examination such as the electrocardiogram From this point of view the ballistocardiograph may be regarded as a research tool that deserves continued exploration On the other hand some investigators regard the ballistocardiogram merely as indicating the degree of elasticity or atheroma of the aorta and hesitate to interpret the ballistocardiogram as a reflection of cardiac output, myocardial strength or coronary disease[11]

Many years of study and correlation may be necessary to determine whether ballistocardiography may be of value as a useful diagnostic or prognostic aid in clinical practice For the present, its general availability renders it simple for the physician or cardiologist to continue to make observations of his own in an effort to correlate them with other better established diagnostic techniques and with clinical progress Until such correlation is unequivocally determined the physician should carefully avoid the danger of rendering a specific diagnosis or prognosis in any individual case based on ballistocardiographic findings or of recommending any specific form of therapy because of such findings

Ballistocardiography may prove to have some statistical merit when applied to large groups of subjects in industrial or insurance medicine,[2, 24] although no conclusive significance may be attached to findings in any individual case Thus it may be found that 1000 individuals at a given age with normal

ballistocardiograms have a much better record of longevity than 1000 individuals of identical age with abnormal ballistocardiograms, yet a similar prognostic conclusion may be erroneous when applied to single persons in either group. Abnormal ballistocardiograms have been noted in the vast majority of patients with angina pectoris, yet it would be improper to conclude that chest pain in a given person represented angina pectoris because his ballistocardiogram was abnormal

In the past the ballistocardiogram has been widely used to measure the stroke output from the amplitude and areas of the I-J stroke[4] [illegible] But although the I-J waves are definitely related to ventricular ejection they are more distinctly determined by the velocity than by the quantity of blood ejected In heart failure the velocity of ejection may be reduced much more strikingly than the quantity while in shock the ejection velocity may be increased although the stroke output is greatly diminished In either circumstance the stroke output determined from the ballistocardiogram will suffer a large error[27]

The ballistocardiogram has also been used to study the effect of various drugs and operative procedures

PHONOCARDIOGRAPHY—HEART SOUNDS

Phonocardiography is the technique of recording the cardiac sounds The phonocardiograph is composed of a stethoscope-like chest piece with a piezoelectric crystal microphone which picks up the vibrations of the heart sounds and transforms them into a varying electrical output according to the stresses imposed by the sound waves The electrical output is then amplified by a stethograph amplifier and finally is recorded by a device incorporated in the electrocardiograph A simultaneous electrocardiogram serves to time the cardiac sounds but for distinguishing special sounds such as a split second sound third heart sound the opening snap of the mitral valve or a gallop sound phlebograms or a carotid artery tracing or electrokymogram may be necessary for correct timing

Stethoscopic and logarithmic phonocardiographs are generally used[90] The *stethoscopic phonocardiograph* records all the sound vibrations brought to the ear when the stethoscope is used audible and inaudible but the very slow vibrations are filtered out The audible vibrations due to cardiac activity are usually those with a frequency of 40 to 100 vibrations per second and under pathologic cardiac conditions up to 1000 per second whereas those below 20 per second are inaudible In the *logarithmic phonocardiograph* the low pitched sounds (low frequency vibrations) which in the ordinary stethoscope arrive at the ear but are not readily perceived are not recorded, only the audible sounds are visually reproduced in this phonocardiogram By means of a distortion yielding a logarithmic type of amplification a record is obtained comparable to the clinical impression of the heart sounds by the human ear with emphasis on the high frequency vibrations

The stethoscopic phonocardiogram not only should be employed for recording the normal heart sounds, but also it is preferred for recording low pitched murmurs such as the apical diastolic rumble of mitral stenosis The logarithmic microphone is preferred for recording high pitched murmurs such as the diastolic murmur of aortic or pulmonary insufficiency In the more modern phonocardiograms such as the Sanborn twin beam and polybeam either stethoscopic or logarithmic records can be obtained with a single microphone, by means of a switch which changes the electrical system The chest piece may be an open bell type which is more efficient for low pitched sounds, or a diaphragm bell which is more effective for high pitched murmurs

There is a third type of microphone, termed a *linear microphone* which records all the chest wall vibrations initiated by cardiac action without distortion In practice this records essentially only the slow vibrations because of their greater amplitude Therefore this microphone is used in cardiography to record chest wall pulsations

Phonocardiography has been of great help in the analysis of the auscultatory findings in the normal and diseased heart [illegible] Phonocardiography may be used to record the fetal heart sounds[8] [illegible] Occasionally it may be needed to distinguish the various sounds of mitral stenosis (to differentiate between a reduplicated second sound the opening snap of the mitral valve or a third heart sound) or to distinguish between a gallop rhythm and reduplicated first heart sound or between a third heart sound and protodiastolic gallop or between a systolic click and an apical murmur

of mitral insufficiency As a rule, however it is not employed with any regularity in the clinical practice of cardiology It is not a substitute for the art of auscultation

For teaching purposes heart sounds have been recorded by a sensitive microphone on phonograph discs which may be readily played back as desired More recently heart sounds have been recorded on tape and played back by tape-recording machines Many advantages accrue from the ability to splice the tape especially the ability to isolate individual heart sounds or murmurs for careful analysis and concentrated audition Recent studies of heart sounds have been made by the method of sound spectrography [56-73] The records disclose the frequency spectrum of the heart sounds as well as their intensity and duration in greater detail than is afforded by conventional phonocardiographs Time is on the abscissa as in the conventional phonocardiogram but the ordinate is frequency, not intensity Intensity is portrayed by the degree of blackness in the recording (Fig 28)

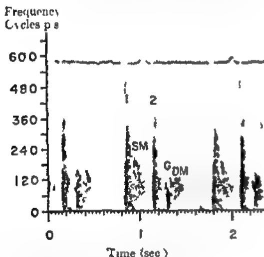

Fig 28 Spectral phonocardiogram Apical recording in patient with rheumatic fever 1 First sound 2 second sound SM systolic murmur DM diastolic murmur G gallop (From McKusick Victor A et al Circulation vol 11 1955)

THE NORMAL HEART SOUNDS[87-90] (Fig 29)

First Heart Sound

The first heart sound occurs early in ventricular systole beginning about 0 02 to 0 04 second after the onset of the QRS complex of the electrocardiogram The main portion of the first sound complex in the phonocardiogram is composed of large irregular fine vibrations with small coarse vibrations preceding and following these The total duration averages 0 14 to 0 15 second, but is briefer in children [88] The first heart sound is due essentially to the sudden tension of the previously lax cusps during closure of the atrioventricular valves [65] Other elements said to contribute to the first heart sound are (1) residual vibrations due to atrial contraction causing the initial vibrations of the first heart sound [66] (2) vibrations due to ventricular muscular contraction, (3) vibrations due to opening of the semilunar valves and vibrations set up by the blood expelled during ventricular systole

The first sound tends to be loud in youth in those with a thin chest wall and in persons with hyperthyroidism mitral stenosis and hypertension Conversely the first sound is apt to be faint in older subjects and in those with pulmonary emphysema pericardial effusion mitral regurgitation shock or severe myocardial disease especially myocardial infarction With complete heart block there is a varying intensity of the first heart sound, depending on the time relations of the atrial and ventricular contractions The first heart sound is usually louder in subjects with a low normal P-R interval than in those with a high normal P R interval These observations suggest that the intensity of the first sound is related to the position of the atrioventricular valves at the onset of isometric contraction or to the speed and consequent impact of their closure which in turn may depend on the speed of the rise in intraventricular pressure in relation to atrial pressure It is presumed that when the ventricles contract very rapidly after the atria the valve cusps are low down in the ventricles and relaxed ventricular contraction then causes them to close with a greater snap and a louder sound When there is a longer interval between atrial and ventricular contraction the cusps have been floated up toward the atrioventricular orifice, are already somewhat tensed when the ventricles contract, and closure of the valve yields a fainter sound

Splitting or reduplication of the first sound may occasionally be heard at the apical region of the heart when there is an exaggeration of the normal asynchronism in the closure of the mitral and tricuspid valves owing to electrical or mechanical factors [75] As

Fig 29 Normal heart sounds Upper tracing phonocardiogram at apex Lower tracing simultaneous electrocardiogram S = first heart sound As = atrial sound of low amplitude inaudible as distinct sound S_2 = second heart sound S_3 = third heart sound A functional systolic murmur inaudible to ear follows the first sound in this phonocardiogram

a rule this is of no clinical significance but may be mis interpreted as a presystolic murmur Splitting of the first sound may be heard in bundle branch block or other conditions in which there is delay in activation of one ventricle relative to another, e g premature ventricular contractions

Second Heart Sound

The second heart sound occurs at the end of systole, its recorded peak coinciding with the end of the T wave of the electrocardiogram or slightly beyond that point It is composed of a large, high pitched diphasic or triphasic wave with small inaudible low pitched vibrations preceding and following the main wave [20, 37] It is produced essentially by the closure of the semilunar valves Low *pitched vibrations due to blood eddies in the* ventricle and the arteries associated with the fall in pressure at the onset of diastole and weak vibrations due to the subsequent opening of the atrioventricular valve may also be recorded with the stethoscopic phonocardiograph The interval between the first and second sounds is briefer than that between the second sound and the *following first sound* because of the usually briefer duration of systole relative to diastole The average duration of the second sound is 0 10 to 0 12 second but below the age of four it averages only 0 06 second

The second sound may be accentuated normally especially in young individuals The intensity of the second sound depends in part on the pressure in the aorta and in the pulmonary artery at the onset of diastole But other factors are important since the pulmonic second sound may be as loud or louder than the aortic when the pressure is lower in the former Perhaps the intensity is more dependent on the relation of the aortic and pulmonary artery pressures to the pressures within their respective ventricles and the speed of the fall in gradient between them Other possible significant factors are the speed and quantity of blood flow the physical state of the semilunar cusps and the ease of transmission of vibrations to the surface of the chest wall depending in part on the position of the aortic and pulmonary valves

The second pulmonic sound is frequently *loud in young healthy persons The aortic* second sound is usually accentuated in systemic hypertension whereas the second pulmonic sound is accentuated and may be louder than the second aortic sound in patients with pulmonary hypertension, especially mitral stenosis in certain congenital cardiovascular lesions in pulmonary congestion *due to left* ventricular failure and in cor pulmonale

A diminution in intensity or absence of the second heart sound may be due to loss of pliability and mobility of the valve cusps or to relatively low pressure in the pulmonic artery Thus the second aortic sound is weak or absent in aortic stenosis and the second pulmonic in pulmonic stenosis

Splitting of the second sound, heard at the base of the heart is due to an asynchronism in closure of the pulmonary and aortic valves [85] It may occur normally in inspiration as a result of the discrepancy in stroke volume of the two ventricles and consequent asynchrony in ventricular contraction and semilunar valve closure The pulmonic sound may be reduplicated in mitral stenosis and the aortic in hypertension Splitting of the second sound may occur more commonly than splitting of the first sound in bundle branch block Splitting of the second sound also occurs in most cases of significant interatrial septal defect, in severe mitral regurgitation, and in respiratory disease resulting in exaggerated cyclic variations in intrapleural pressure [85] Inspiration tends to intensify splitting of the second sound in right bundle branch block and to diminish or eliminate it in cases of left bundle branch block [85]

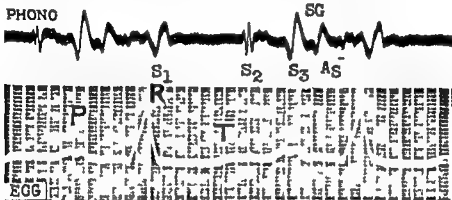

Fig 30 Gallop rhythm Exaggerated S_3 causes diastolic gallop sound Exaggerated A_S causes presystolic gallop sound Their proximity in this case caused a fusion or summation gallop sound (SG) in diastole

Third Heart Sound

The third normal heart sound,[74, 96] usually audible only in children or young adults with a thin chest wall is composed of weak vibrations of low frequency It is best recorded at the apex in the left decubitus position [70] It is produced by the vibrations set up in the ventricles during the rapid inflow phase of early diastole It usually occurs about 0 05 to 0 1 second after the end, or 0 15 to 0 17 second after the beginning of the second heart sound It follows the V wave of the phlebogram but occasionally coincides with it The possible role of the pericardium in the production of a third heart sound has been suggested as a result of study of a case of calcified pericardium [69]

Fourth Heart Sound

An atrial or fourth heart sound[87, 90] is rarely audible under normal circumstances but may be recorded occasionally in the phonocardiograms of children with a thin chest wall or in complete heart block It is believed to be produced by atrial contraction, by the passage of blood through the atrioventricular valves and by the distention of the ventricles by the rapid inflow of blood in mid diastole [98] Atrial sounds are best recorded at the apex, but sometimes may be recorded in the third or fourth left interspace

GALLOP RHYTHM

This refers to a rhythm with an accentuated extra sound besides the two normal sounds, the three sounds creating the auscultatory effect of a canter As a rule gallop rhythm is heard only in the presence of a rapid heart rate

There are three main types of gallop rhythm (1) the protodiastolic, (2) the presystolic and (3) summation gallop In addition there are instances in which an extra sound of uncertain origin occurs during systole This has been termed systolic gallop or systolic click, but its mechanism and significance differ greatly from those of the usual forms of gallop rhythm

It is important to identify the position of the extra sound in order to differentiate the diastolic forms of gallop, which usually denote serious myocardial disease, from the systolic gallop which is of little or no clinical significance When the cardiac rate is very rapid, the "presystolic" gallop sound may become mid diastolic or protodiastolic because

of the shortening of diastole and may thus be indistinguishable from a protodiastolic gallop

Protodiastolic Gallop Rhythm

The extra or gallop sound occurs early in diastole during the phase of rapid filling of the ventricle (Fig 30) It coincides in time with the occurrence of the *third heart sound* i e about 0 16 to 0 2 second after the second heart sound [65] In fact the protodiastolic gallop is most generally believed to represent an accentuated third heart sound[77, 100] and to be due to a similar mechanism [71]

Protodiastolic gallop occurs in left ventricular failure and is believed to result from the very rapid inflow of blood during early diastole into a dilated, flabby left ventricle The sound is caused by the resulting vibrations of the ventricular wall by its impact on the surrounding tissues and chest wall [100] or less likely by vibrations of the mitral valve [81] The high pulmonary venous and left atrial *filling pressure in left heart failure* and acceleration of the heart rate are factors which intensify the phase of rapid ventricular filling and predispose to protodiastolic gallop This type of gallop occurs even with atrial fibrillation since *it is not dependent on atrial contraction*

Protodiastolic gallop rhythm is usually heard best with the patient recumbent and the heart rate accelerated and is located at the apical region in left ventricular dilatation and to the left of the mid or lower sternum in right ventricular dilatation

A distinct third heart sound resembling protodiastolic gallop is heard occasionally in children and young adults But a protodiastolic murmur after the age of thirty is usually due to left ventricular failure or less commonly to right *ventricular failure* Associated evidence of cardiac disease and left ventricular failure supports the interpretation of a gallop rhythm rather than of a normal third heart sound According to Bramwell [64] a *third heart sound, unlike gallop rhythm* is not palpable and may be heard at normal cardiac rates

Presystolic Gallop Rhythm

The gallop sound occurs just prior to the first heart sound preceding it by at least 0 08 sec (Fig 31) It coincides with atrial systole and is believed to represent an accentuated atrial sound [77, 88] The atrial origin of this type of gallop sound is supported by its disap-

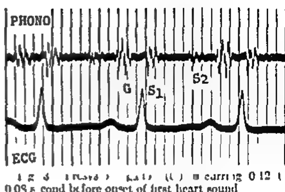

Fig 31 Presystolic gallop (G) occurring 0 12 to 0 08 second before onset of first heart sound

pearance or failure to occur in the presence of atrial fibrillation

When the P R interval is prolonged or when *there is very pronounced tachycardia* the atrial gallop sound is displaced in the shortened diastole and it may be mesodiastolic or protodiastolic The presystolic murmur of mitral stenosis the opening click of the *mitral valve and an audible atrial sound* when there is tachycardia and a prolonged P-R interval may have to be differentiated from gallop rhythm Phonocardiographic tracings are often necessary The Austin Flint murmur *(p 689) has been interpreted as presystolic* gallop rhythm [77]

Summation Gallop (Fig 30)

This is the most common form of gallop rhythm and results from the coincidence of the third heart sound and the atrial sound or of protodiastolic and presystolic gallop sounds Prolongation of the P R interval and pronounced tachycardia are responsible for this coincidence Summation gallop may occur as a result of left or right ventricular failure combined with tachycardia but also occurs in normal persons with tachycardia or in patients *with rheumatic fever* who exhibit tachycardia and a prolonged P R interval

Systolic Click (Gallop) (Fig 32)

The extra or gallop sound has a sharp clicking quality and is heard between the first *and second sounds* [68, 72, 89, 90] *It may be due* to vibrations set up in a dilated aorta or pulmonary artery or to pleuropericardial adhesions or other extracardiac factors [91] The clicks associated with dilatation of a great artery as in essential hypertension or atrial septal defect usually occur early in systole whereas those associated with previous pericarditis and other extracardiac mechanisms usually occur late in systole

THE OPENING SNAP OF MITRAL STENOSIS

This sound occurs very shortly after the second sound and must be distinguished from a reduplicated second sound, from the physiologic third heart sound and from gallop

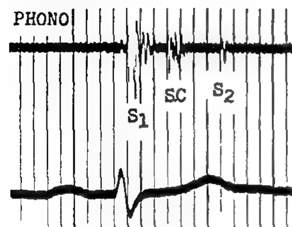

Fig 32 Systolic click (S C) also termed systolic gallop in a 53 year old man with pleuropericardial adhesions

rhythm For details and differentiation see p 659 The phonocardiogram in conjunction with a simultaneous jugular venous pulse tracing or apex cardiogram is important in this differentiation (Fig 33)

CARDIAC MURMURS

Cardiac murmurs are represented on the phonocardiogram usually as a series of vibrations of varied pitches So-called musical or sea gull murmurs (p 688) are recorded as a series of regular vibrations of the same frequency

Systolic Murmurs

Systolic murmurs may be revealed as vibrations merely prolonging the first sound or they may be much more distinct and of greater intensity Leatham[79] classifies systolic murmurs as (1) ejection murmurs (aortic stenosis, pulmonic stenosis), which occur predominantly in midsystole, and (2) regurgitant murmurs (mitral and tricuspid insufficiency) in which the murmur occurs usually throughout systole (pansystolic) The apical systolic murmur of mitral regurgitation is usually a decrescendo murmur with greater vibrations at first diminishing in intensity and ending long before the second sound The vibrations are of varied pitch chiefly of high frequency Occasionally the murmur is composed of high frequency vibrations and lasts throughout most of systole Phonocardiography is no more helpful than auscultation in determining whether there is a significant mitral regurgitation in patients with mitral stenosis who are being considered for mitral commissurotomy

The systolic murmur of aortic stenosis is often recorded as a diamond shaped series of vibrations beginning after the first sound at the aortic area, increasing in amplitude toward the middle of systole diminishing again thereafter and ending before the onset of the second sound which may be absent This distinctive pattern when recorded at the apex may serve to distinguish from mitral regurgitation those occasional cases of aortic stenosis with a murmur heard only or best at

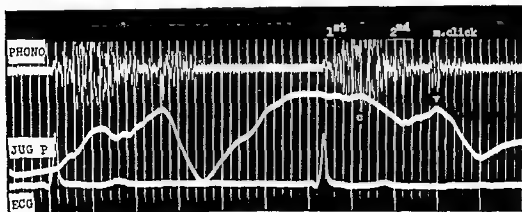

Fig 33 Opening snap (apical area) in a case of mitral stenosis Note occurrence of opening snap or mitral click (m click) at peak of V wave of jugular venous pulse tracing Systolic and diastolic murmurs follow first sound and second sound respectively

the apex of the heart. There may also be a loud series of systolic vibration lasting through all of systole and heard in the second left or second right interspace in cases of aortic or pulmonic stenosis. Pulmonic systolic murmurs in apparently normal children are recorded as a simple wave of measurable frequency with sporadic distortions.[illegible] *Musical murmurs* may have a concertina like pattern on the phonocardiogram with increasing and diminishing intensity of vibrations but with frequencies which are identical or only slightly varied. These murmurs may be noted in cases of myocardial infarction and calcific aortic stenosis and following rupture of a valvular cusp or a papillary muscle.

Apical Diastolic Murmurs

Apical diastolic murmurs indicative of mitral stenosis are shown by phonocardiograms to consist essentially of low frequency vibrations, which account for their rumble quality (Fig 33). The murmur may begin early in diastole, continue into mid-diastole and even merge with the increased vibrations of a presystolic murmur. Or the rumble may be limited to early diastole or to mid diastole—most often the latter. There may be only the low pitched vibrations with increasing intensity and merging into the first sound which represent the typical crescendo murmur of mitral stenosis. However phonocardiograms have shown that the vibrations producing this murmur may diminish before the following first sound and that the crescendo effect is present because of the sharp first sound terminating a diminishing murmur. The phonocardiogram may be useful in distinguishing this presystolic murmur by its time relationship with a simultaneous electrocardiogram from so-called pseudo-presystolic murmurs which are really modified first sounds simulating murmurs[62] and which are apt to be heard in cases of hyperthyroidism and an overacting heart. When the murmur of mitral stenosis is limited to a very small area near the cardiac apex and when it is audible only with acceleration of the cardiac rate and with the patient in the left lateral position the phonocardiogram may be no more perceptive than the ear unless these conditions are satisfied and the bell of the phonocardiograph is properly placed.

The phonocardiograph has not demonstrated any clear difference between the presystolic murmur of mitral stenosis and the Austin Flint apical presystolic murmur of aortic regurgitation.[67] However, a distinction may be made by other features of the tracing including the opening mitral snap and the character of the first sound at the apex and the second sound over the pulmonic area.

Basal Diastolic Murmurs

Diastolic murmurs at the base, due to aortic or pulmonic insufficiency, show high frequency vibrations of low or moderate intensity which begin early in diastole and diminish in intensity usually terminating in mid-diastole.[illegible] Louder and more prolonged murmurs are apt to occur with syphilitic bacterial endocarditic dissecting aneurysmal and traumatic forms of aortic regurgitation than with the rheumatic form. Occasionally a sea gull cry type of aortic diastolic murmur is heard in syphilitic aortic insufficiency with everted aortic valve but also in the aortic insufficiency associated with bacterial endocarditis or trauma. (See Chapter 27.) In these the murmur is represented by regular vibrations of uniform frequency.[75] The phonocardiogram does not differentiate the murmur of pulmonic from that of aortic insufficiency.

Continuous Murmurs

Continuous murmurs often described as machinery like humming top wind mill or tunnel murmurs found in patent ductus arteriosus arteriovenous fistulas and rupture of a syphilitic aortic aneurysm into the pulmonary artery are represented by large vibrations varying often in intensity and frequency and extending throughout systole and diastole. The vibrations usually increase in intensity at the end of systole mask the second sound and diminish in diastole.

Pericardial friction rubs are recorded as vibrations of varied pitch but usually of high pitch during systole and diastole (Fig 34).

THE JUGULAR VEIN TRACING (VENOUS PULSE)

Although the electrocardiogram has almost entirely eliminated the clinical use of the jugular vein tracing (phlebogram) the latter is still important in timing certain events in the cardiac cycle and may be of aid in diagnosing cases of organic and functional tricuspid insufficiency or tricuspid stenosis and certain arrhythmias especially when the P wave in the electrocardiogram is obscured.[106, 105, 11]

With the subject in the supine position or semirecumbent if he is orthopneic, a special applicator in the form of a double-rim circular cup is applied to the right jugular bulb, where it is held to the skin by suction created in the outer chamber of the cup[107] The inner chamber picks up the venous pulsations, which transmit pressure changes to a crystal type, linear microphone which in turn converts them into electrical waves The latter pass through an amplifier and are then recorded with the aid of a camera The patient should hold his breath during the recording least in part to transmission of the underlying carotid pulse or to transmission of the pulse of the ascending aorta or arch of the aorta to the superior vena cava and thereby to the jugular vein The beginning of the upstroke of the "c" wave falls about 0 14 second later than the onset of the QRS in an electrocardiogram taken simultaneously

The *third positive wave the "v" wave* or "early diastolic wave" mirrors the rise in volume and pressure in the right atrium as it fills at the end of systole and the early part of diastole just before the tricuspid valve opens

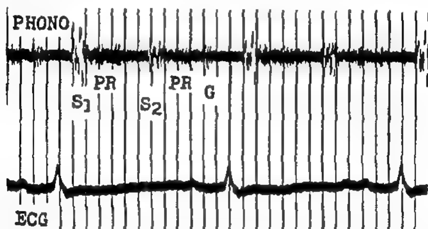

Fig 34 Pericardial rub (PR) in systole and early diastole associated with presystolic gallop (G)

The Normal Jugular Venous Pulse (Fig 35)

Normally there are three positive waves in the jugular venous pulse tracing[108, 104, 101] These pulsations are determined essentially by pressure and volume changes in the right atrium which are reflected by corresponding alterations in the jugular vein

The *first or "a" wave* occurs shortly before the apical impulse and is due to right atrial contraction It is absent in atrial fibrillation It is exaggerated with simultaneous contraction of the atria and ventricles which causes regurgitation of blood into the venous system as in heart block nodal rhythm or nodal premature beats It is also prominent in tricuspid stenosis with regular sinus rhythm and in tricuspid insufficiency In cases of interatrial septal defect there is a double A wave due to the left-to right shunt as well as to atrial contraction[10]

The *second or "c" wave*[109] or "systolic wave" is a slight peak due to elevation and closure of the tricuspid valve at the onset of ventricular systole but it has also been attributed, at

The "v" wave is also called the stasis wave and is especially exaggerated in cases of right heart failure The downward limb of the "v" wave represents the fall in atrial and venous pressure as the tricuspid valve opens

Between the positive "c" and "v" wave peaks i e throughout most of ventricular systole the jugular vein empties almost completely into the superior vena cava and right atrium and venous tracings show a pronounced depression or negative wave termed "x" (systolic collapse) Because this venous collapse is the most striking feature of the normal venous pulse, the latter is termed a *negative venous pulse* The "x" depression in systole is due to the aspirating effect on the blood in the veins when blood is expelled from the thoracic cavity and the tricuspid valve and atrioventricular septum are drawn down in systole When the right atrial pressure is elevated in right heart failure and especially in tricuspid regurgitation the "x" descent is greatly diminished or is replaced by a positive wave (positive venous pulse) (See

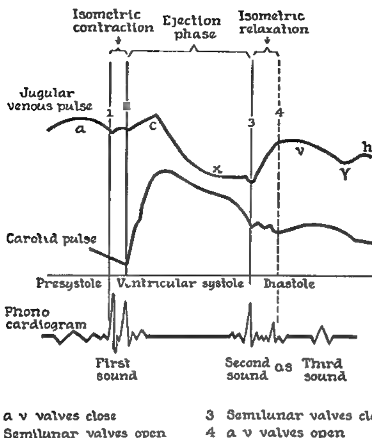

Fig 35 Relation of waves in jugular venous pulse tracing to events in cardiac cycle as seen in carotid pulse tracing and phonocardiogram

Chapter 29) Following the "v" wave there is a negative depression ("y" wave, diastolic collapse) This represents the emptying and fall in pressure in the right atrium after the tricuspid valve opens and before atrial contraction Following the "y" there may be another small positive wave, the "h" wave attributed to floating up of the tricuspid valve prior to atrial contraction

HEPATIC PULSE TRACING

The hepatic pulse tracing is essentially like that of the jugular venous pulse but the "c" wave seen in the jugular venous pulse tracing is virtually absent in the hepatic pulse tracing A cup attached to a linear microphone is applied to the right hypochondrium if the liver is enlarged, or on the right side of the epigastrium in normal persons and held in place by a rubber strap

Normal Hepatic Pulse[108, 111]

The normal hepatic pulse tracing shows a presystolic "a" wave occurring during atrial contraction and virtually simultaneous with the "a" wave of the jugular pulse This is followed by a deep negative wave ("x") representing systolic collapse as the liver empties into the inferior vena cava and right atrium during ventricular systole The systolic collapse is followed by a "v" wave representing the increase in hepatic volume until at the peak of the "v" wave the tricuspid valve opens The descending limb of the "v" leads to another negative wave the diastolic collapse ("y") The major waves "a" and "v" of the liver pulse are recorded approximately 0 02 and 0 04 second later than their corresponding waves in the phlebogram In addition to these major waves there may be smaller notches due to transmitted impulses from the heart through the diaphragm A small positive notch may occur in early systole

Positive (Systolic) Liver Pulse

A prominent positive wave during systole instead of the normal systolic collapse (negative wave) occurs in a variety of conditions

in which a rise in right atrial pressure during ventricular contraction is transmitted as a pulse to the inferior vena cava and liver Most frequently, a positive systolic wave is observed in functional or organic tricuspid insufficiency (p 714) Thus it is noted especially with rheumatic mitral stenosis and in coronary heart disease when these are complicated by advanced right heart failure I have observed it in cases of cor pulmonale and severe right heart failure and in cases of congenital heart disease Rarely in nodal rhythm atrial contraction simultaneous with ventricular contraction produces a positive liver pulse The positive liver pulse is associated with a palpable systolic pulsation or expansion of the liver

Presystolic Liver Pulse (See also p 715)

In cases of tricuspid stenosis, usually associated with severe mitral stenosis and also in other conditions[110, 103] (p 715) the rise in right atrial pressure during atrial systole is transmitted to the hepatic inferior vena cava and hepatic veins and may give rise to an extremely exaggerated a wave and a palpable presystolic liver pulsation Usually however tricuspid insufficiency is associated with the tricuspid stenosis and the systolic pulse of the former dominates the liver pulse tracing and obscures the presystolic pulse When atrial fibrillation is present there is no presystolic 'a wave or pulse (see also p 715)

CARDIAC CATHETERIZATION—TRACINGS OF INTRACARDIAC AND INTRA VASCULAR PRESSURE

The procedure of cardiac catheterization[1, 9, 116, 1 5, 120, 118] is included here because graphic methods are used to record the pressures in the various cardiac chambers and great vessels Actually the technique serves to record pressures to determine the oxygen content, to discover an abnormal passage which the catheter may enter and more recently to introduce contrast material for selective visualization of specific portions of the heart or great vessels Cardiac catheterization has been widely used to make physiologic observations which have had many important clinical applications, particularly in congenital heart disease mitral stenosis cor pulmonale and during pregnancy (*For details as to the role of* cardiac catheterization in individual diseases and appropriate bibliography see sections on specific diseases)

RIGHT HEART CATHETERIZATION

Indications

Since to a large extent right heart catheterization *is still a research tool*, it is indicated *and performed in order to obtain further* physiologic observations and to correlate these with clinical data From the clinical viewpoint it is indicated whenever required to establish a definite specific diagnosis This has become increasingly important as cardiac lesions have become amenable to surgical correction, by confirming or excluding a tentative diagnosis catheterization has served to confirm the desirability of a surgical procedure or to prevent an unjustifiable thoracotomy

The widest clinical application has been in congenital heart disease especially for the diagnosis of atrial and ventricular septal lesions, pulmonic stenosis and patent ductus arteriosus without the typical murmur Catheterization has been particularly useful with infants and very young children in whom the diagnosis of congenital cardiac lesions by physical diagnosis conventional x ray study and electrocardiography is notably difficult It has been used with increasing frequency recently in cases of mitral stenosis and other acquired valvular defects chiefly to study the circulatory dynamics and to follow the pathologic physiology during the natural history of the lesion and after commissurotomy Such studies have also indicated a possible practical clinical application they may aid in determining the type of case likely to benefit from this surgical procedure namely the patient with pulmonary artery hypertension and a high atrioventricular gradient

Preparation and Premedication of the Patient

The procedure its need and the minimal risk involved are explained in general terms to the adult patient or to the parent of a child Permission is obtained in writing When possible and desirable the patient is brought to the catheterization laboratory on the day preceding the procedure in order to familiarize *him with the staff the surroundings and the* equipment When the respirometer or the bicycle ergometer is to be used for physiologic studies, the patient is instructed in its use *and permitted trial performances until he* breathes evenly at rest and during exercise on the bicycle ergometer

The evening before catheterization the pa

tient is given 600 000 units of aqueous procaine penicillin intramuscularly (proportionally less for infants and young children and this dose is repeated thereafter every 12 hours for four days after the procedure Breakfast is withheld on the morning of catheterization and 0 1 gm of Nembutal is administered orally one hour before catheterization

General anesthesia by means of rectal Avertin and subcutaneous atropine followed by an intravenous drip of Pentothal sodium has been found necessary in infants and young children in order to assure cooperation and maintenance of the steady state However some groups of workers premedicate children up to the age of eight years with morphine sulfate 1 mg (1/64 grain) per 10 pounds of body weight and sodium phenobarbital 30 mg (½ grain) per 10 pounds of body weight one-half to one hour before the procedure and only occasionally supplement this during catheterization by Seconal intravenously 0 5 to 1 0 mg per pound of body weight [19]

The patient is brought to the laboratory by wheel chair or stretcher and is examined to exclude any complication especially an intercurrent infection or an intensification of heart failure

Technique[17 18]

Catheterization is performed by a team of several physicians a nurse and one or more technicians to analyze blood samples and samples of expired air One physician performs the actual insertion and manipulation of the catheter and withdrawal of blood samples from the catheter a second performs the fluoroscopy to control the position of the catheter during its various manipulations inserts the indwelling arterial needle and withdraws samples from it and also supervises the use of the respirometer while a third physician handles the apparatus by which he records pressures from the catheter and arterial needle observes the electrocardiographic record on the oscilloscopic screen and reports the occurrence of any arrhythmia or other abnormality

The pressure recording apparatus is set up and calibrated It consists of Statham gauge transducers with a four channel oscilloscopic recorder The manometers are connected through fluid filled tubing at the proper levels to a three way stopcock attached to the proximal end of the catheter and to the indwelling arterial needle An optical system transmits the pressure deflections to a camera which records the pressures on film moving with a speed of 50 to 75 mm per second A simultaneous electrocardiographic tracing may be made

The patient lies supine on the fluoroscopic table which is covered by a pad or sponge rubber mattress The operator wears a lead apron and scrubs and dons sterile gown and gloves as for a surgical procedure Following local 2 per cent procaine anesthesia a percutaneous puncture of the brachial artery is made with a special No 22 or No 20 indwelling arterial needle (Becton Dickinson and Co Rutherford N J) to which a three way stopcock is attached It is left in place and kept patent with a constant drip of dilute aqueous heparin in a solution of 5 per cent dextrose in distilled water Blood samples and pressure readings are made by appropriate turns of the stopcock

An antecubital vein is selected in adults or older children the right or left saphenous vein in infants and young children and the field is sterilized with Merthiolate and properly draped with sterile sheet and towels A cut down is performed under 2 per cent procaine anesthesia if no general anesthetic has been administered the vein is isolated ligated and incised proximal to the ligature A No 6F or 7F flexible radio-opaque catheter made of nylon with unwettable plastic covering 100 cm long with a curvature near the entering tip a hole at the tip and an adapter for a three way stopcock at the outer end (supplied by U S Catheter and Instrument Co Glens Falls N Y) is autoclaved at least some hours before use The catheter is inserted through the incision in the vein and advanced under fluoroscopic control into the superior vena cava and progressively into the pulmonary artery or its smallest ramification for pulmonary capillary pressure measurement If obstruction is encountered at any point further progress is made by rotation of the catheter and by slight withdrawal and advancing the catheter again Spot x ray films are taken to verify the position of the catheter when there is uncertainty as to its location or when it enters an abnormal vessel or chamber

Patency of the catheter is maintained by a constant drip as described for the indwelling arterial needle Fluoroscopy is carefully timed and limited preferably to less than ten

minutes, with an absolute maximum of twelve minutes.

The tip of the catheter is led along the walls of the pulmonary artery, the right ventricle and the right atrium during its stay in these regions. One may thus determine whether there is a stenosis of the pulmonary valve or conus (infundibular stenosis) or whether the catheter passes through a patent ductus arteriosus into the aorta. When the catheter is in the right ventricle the size of this chamber can be assessed. The aorta may be entered in tetralogy of Fallot or dextraposition of the aorta. In the right atrium one may enter an atrial septal defect or a pulmonary vein which empties into the right atrium. The catheter may also be passed into the coronary, hepatic or renal veins and their content of blood gases and other substances determined to study the metabolism of the heart, liver or kidney respectively.

Blood samples from the catheter and pressure recordings are not taken until the catheter has been advanced to the farthest point desired, otherwise further introduction of the catheter may be prevented by venospasm before passage has been completed. However, if in its initial passage the catheter is introduced into a pulmonary vein, left atrium or ventricle or aorta, blood samples and pressures are immediately taken from these locations. Furthermore, reports of abnormal changes in pressure or of gas analyses made during the procedure may indicate the desirability of repeated determinations or tracings or a change in routine procedure. As the catheter is withdrawn, samples of blood are aspirated and pressures recorded from each successive vessel and chamber including the pulmonary artery and branches, outflow tract of the right ventricle, midportion or apex of right ventricle, tricuspid area of right ventricle, tricuspid area of right atrium, mid right atrium, superior vena cava and inferior vena cava near the right atrium. Arterial blood samples and pressure recordings are taken simultaneously from the indwelling arterial needle.[2]

The oxygen and carbon dioxide content of the blood is determined by the method of Van Slyke and Neill (Chapter 10). The blood samples are carefully drawn from catheter and arterial needle by a Luer Lok syringe with great care to avoid air bubbles from entering the circuit or the syringe. After rotation of the blood in the syringe, it is transferred to Ostward Van Slyke pipettes under airtight conditions and the determinations carried out promptly. If desired, the syringes with blood samples are stored in ice for later determinations. The oxygen content is determined and then the oxygen capacity. Oxygen saturation is calculated by dividing content by capacity.

The oxygen consumption is determined by the closed method using a modified standard metabolism apparatus such as the Collins respirometer or preferably by the open method in which samples of expired air are collected by facial mask or mouthpiece and nose clip into a Douglas bag or Tissot spirometer and analyzed for their gaseous content (Chapter 39).

At the end of the procedure the catheter is withdrawn slowly by steady tension, the ligature on the antecubital vein is removed, bleeding controlled by pressure, the skin incision closed by flamed adhesive and a sterile dressing applied. If the saphenous vein was used, it is tied near its junction with the femoral vein and the skin sutured. The arterial needle is withdrawn and hemostasis effected by immediate pressure for at least five minutes.

Complications

There is surprisingly little risk in the procedure of cardiac catheterization, especially when one considers that the subjects are usually seriously ill cardiac patients. There were 4 fatalities among 5700 instances of right heart catheterization.[1, 4] Great care should be taken to avoid air embolism, especially in patients with right to left cardiac shunts, but despite this potential danger, air embolism has been a great rarity. Pulmonary thrombosis may occur.[139]

Cardiac arrhythmias are the commonest complications of cardiac catheterization, chiefly premature beats but rarely paroxysms of supraventricular tachycardia, runs of ventricular tachycardia, atrial fibrillation and right bundle branch block.[138, 130] The extrasystoles are particularly likely to occur when the catheter passes through the tricuspid valve or contacts the ventricular septum near the outflow tract, or if excessive suction is produced in taking samples of blood from the right ventricle.

Venous thrombosis and possibly, rarely, cardiac endocardial thrombosis occasional

chills and rare instances of pulmonary edema are other complications which have been noted. In young children or infants the amount of blood withdrawn for gas determinations may be large enough to justify blood replacement.

CATHETERIZATION OF THE LEFT HEART AND AORTA

The left side of the heart has been catheterized by introduction of a catheter into the radial artery or brachial artery[130, 136, 137] and retrograde passage of the catheter up the arch of the aorta past the aortic valve and into the left ventricle. The procedure has been associated with various complications including *rupture of the aorta or of an aortic leaflet*, occlusion of a coronary artery and ventricular tachycardia and ventricular fibrillation. Retrograde passage of the catheter via the brachial artery to the aorta only without passing the aortic valve avoids most of the risk and has been used to make direct recordings of the aortic pressure pulses, especially in coarctation of the aorta, aortic insufficiency and hypertension.[138] Catheters have been introduced into the radial or brachial artery and left common carotid artery and contrast material injected for thoracic aortography[1, 3] (p. 17).

Direct simultaneous pressure readings from the left side of the heart may be made and recorded at the time of a cardiac operation by means of a needle inserted into the left atrium, left ventricle and aorta.[1, 1] By introducing a double lumen catheter whose orifices are 10 cm apart so that one lumen is in the left ventricular and the other in the left atrial cavity, simultaneous pressure determinations can be made from these chambers and the pressure differences (gradient) instantaneously derived by electrical subtraction.[1] A variety of other approaches have been made to measure and record the pressures in the left side of the heart and aorta without operation by direct puncture through the chest[115, 112, 136, 1, 35, 145a] or by bronchoscopy[113] (Chap. 26). Goldberg et al.[13] recorded pressures from all chambers of the heart and determined the cardiac output and pertinent gradients in cases of mitral stenosis and of aortic stenosis by simultaneous catheterization of the right heart through a peripheral vein and the left heart by a 6-inch No. 18 needle introduced into the left atrium paravertebrally and followed by a catheter passed through the needle into the left atrium, left ventricle and aorta. A somewhat similar technique was employed by Blakemore et al.[119] to determine the pressure gradient across the mitral or aortic valves as a basis for assessing the degree of stenosis and *selecting patients for appropriate cardiac surgery*. Wood et al.[143] modified available procedures to allow simultaneous measurements of aortic, left ventricular and left atrial pressures along with the blood flow (cardiac output). For accurate interpretation of the pressure gradient across a stenotic valve, the flow across the valve was measured simultaneously with the pressure gradient.

NORMAL PRESSURES IN THE CARDIAC CHAMBERS AND PULMONARY ARTERY

The normal pressures obtained by cardiac catheterization are shown in the table below (see also Fowler et al.[131], Braunwald et al.[1, 1]).

OTHER GRAPHIC METHODS

A variety of other graphic methods have on occasion been employed but have not attained significant clinical usefulness. A few which have been discussed in recent years may be mentioned so that the interested reader may refer to the original reports.

CARDIOGRAPHY—KINETOCARDIOGRAPHY

Cardiac sounds and especially cardiac murmurs are associated with vibrations of the chest wall which are of relatively high frequency. In addition cardiac activity produces so-called slow vibrations of the chest

NORMAL INTRACARDIAC PRESSURES

	SYSTOLIC mm Hg	DIASTOLIC mm Hg	MEAN mm Hg
Right atrium	4 to 6 (5)	−2 to +2 (1)	2 to 4 (avg 3)
Right ventricle	20 to 30 (25)	0 to 4	
Pulmonary artery	20 to 30 (25)	7 to 12 (9)	13 to 18 (avg 15)
Pulmonary capillary			4 to 12 (avg 8)
Left atrium			4 to 8 (avg 6)
Left ventricle		3 to 10 (6)	

wall, which, unlike the vibrations of most cardiac sounds and murmurs, are as a rule readily visible and palpable The slow chest wall vibrations include the apical impulse and other precordial movements which may become especially prominent in cardiac disease

Various devices have recently been employed to record the e vibrations or pulsations over the apical, pulmonic aortic and tricuspid regions and over the epigastrium Johnston and Overy[136] used an electromanometer connected by short hard rubber tubing with a funnel pickup device applied airtight against the chest wall Luisada and Magri[138] employed a linear (crystal) microphone attached by its cable to the electrocardiograph for recording The vibrations of the chest wall are transmitted to the air in a funnel chest piece and thence to the linear microphone, which transforms the air waves into electrical pulsations These are recorded as a continuous tracing by the electrocardiograph s galvanometer Eddleman and associates[1 8] used as their pickup device a sensitive metal bellows with a small metal arm whose end piece is flat and applied airtight to the chest wall The vibrations of the latter are transformed by the bellows in an airtight system into a pulse wave which, in turn, is converted by a piezoelectric transducer into an electric current recorded by an electrocardiograph

The normal pattern of the precordial cardiogram or kinetocardiogram and its variants have been described and distinctly different patterns have been observed in patients with organic heart disease The significance of these differences is uncertain and the method has no clinical importance at the present time

RADIOCARDIOGRAPHY

This is a technique of recording the concentration of intravenously injected radioisotope in the cardiac chambers A Geiger Muller counter is placed over the precordium and the varying number of counts is recorded as a curve by an ink recording device or electrocardiograph Prinzmetal et al[u] injected 10 to 20 millicuries of radiosodium with a half life of 14 to 18 hours while Luisada and associates[137] used 50 microcuries of di iodo fluorescein which has a half life of seven days Shipley et al[145] employed a scintillation counter, which permits the use of very low doses (4 microcuries) of I^{131} albumin to record the radiocardiogram

Within two seconds after the injection, there is a sharp upward wave (R) lasting 3 or 4 seconds, due to the arrival of radioisotope in the right heart chambers This is followed shortly by a second, lower, rounded wave (L) starting 5 to 7 seconds after the injection and lasting about 5 or 8 seconds and due to radioisotope in the left cardiac chamber When the drug has left the heart, the curve returns to the baseline The time of arrival of the radioisotope in the right and left sides of the heart denotes the circulation time, and the concentration is an indirect measure of the residual cardiac blood volume Changes in the curve occur in heart failure, congenital cardiac shunts[134] constrictive pericarditis and vascular obstructions In mild heart failure there is a widening of the interval between the two hump-like waves of the radiocardiogram[145]

RHEOCARDIOGRAPHY[135 141]

During the course of the cardiac cycle the opposition or total resistance to the flow of an alternating current sent through the body i e, the body impedance undergoes rhythmic variation If two electrodes of a high frequency circuit are applied to the body, fluctuations in electrical impedance in the course of the cardiac cycle may be measured and recorded on the electrocardiograph The resulting curve has been termed a rheocardiogram In a recently employed method the body is connected to a generator of high oscillation frequency (14 000 cycles per second) and receives about 20 milliamperes current While the body and series resistor is placed in one branch of the circuit the other branch contains a Wheatstone bridge which measures the impedance between a pair of electrodes placed in the apical region of the heart and at the right shoulder A change in impedance affects the balance of the bridge and the varying bridge voltage is amplified and recorded as a curve by the electrocardiograph

This and similar techniques of measuring rhythmic changes in body impedance (rheocardiography) have also been termed di electrography[114 148] and impedance plethysmography[140] and unfortunately, radiocardiography the latter is not be be confused with the method of radiocardiography described above

The factors re ponsible for the rhythmic change in body impedance are uncertain. They were first attributed to changes in cardiac volume during the cardiac cycle and the rheocardiogram was interpreted as a volume curve of the heart during its various pha es of activity and relaxation. More recent studies indicate that the changes in body impedance are related to rhythmic changes in the caliber or blood content of the body vessels during the cardiac cycle[160, 1 0]. Rheocardiography is of no demonstrated clinical value at the present time.

Dye Dilution Curves have been u ed to local ize cardiovalvular defects[153] (p 666) and de termine the presence of shunts in congenital heart disease[151, 152] (p 798)

PART II

CIRCULATORY FAILURE

Chapter 4

CARDIAC FUNCTION AND CARDIAC FAILURE

DEFINITION

The function of the heart is to maintain an adequate output of blood at all times. Cardiac failure denotes that the output of the heart is insufficient for the needs of the tissues. Thus a normal cardiac output is not a fixed absolute value but must be assessed in terms of variable tissue requirement.

The failing heart may supply an adequate flow of blood when a patient is at rest but not under the stress of exercise, of pregnancy, of fever and infection or of hyperthyroidism. Under certain circumstances, e.g., severe anemia, the cardiac output of the patient at rest may even exceed that of normal individuals.[illegible] [10] Heart failure may be present despite this augmented cardiac output if the latter does not quite compensate for the deficiency in oxygen content of the blood, i.e., if the tissues do not receive their needed supply of oxygen despite an increased blood flow. The adequacy of cardiac function must therefore be defined not only in terms of cardiac output but also in terms of its capacity for performance under various loads.

The definition of cardiac failure in terms of an inadequate cardiac output refers to a deficiency on the arterial side of the circulation. When heart failure is defined in terms of the venous side of the circulation, it denotes an inability of one or more chambers of the heart to accept and expel the venous return throughout the range of physiologic activity. Finally, as we shall see, neither of these definitions is suitable in clinical practice at the bedside. Then cardiac failure is best defined as a clinical syndrome characterized by distinctive symptoms and signs which are the consequences of the above-mentioned disturbances in cardiac output and in cardiac disposition of the venous return.

THE LAW OF THE HEART

Cardiac Response to Increased Venous Inflow

In a controlled circulation, such as the heart lung preparation, the arterial resistance (resistance to outflow) can be kept constant by a clamp on the aorta and the rate of the heart may be maintained constant by an excitatory stimulus whose rate is fixed. The inflow into the heart can be varied by infusions into the external jugular vein and the effects studied by observing the cardiac output, the size of the cardiac chambers and the intracardiac pressure curves.

Patterson and Starling[54] observed that when the venous inflow was increased the intra-atrial and ventricular pressures rose. There was an increase in the diastolic size of the heart due to inability to eject immediately the increased amount of fluid. With the next few heart beats there was a progressive increase in cardiac output until this was equal to the increased inflow and equilibrium was restored. Up to a certain physiologic limit further increase in cardiac inflow resulted in continued increase in diastolic cardiac volume and this, in turn, in an augmented cardiac output.[54] [illegible] In this way the heart was able to adapt itself to respond adequately to an increased inflow of several hundred per cent. When the heart began to fatigue, an augmented inflow caused an enlarged diastolic volume without a concomitant rise in cardiac output and the heart no longer ejected as much blood as it received. This deficiency was denoted by a rise in venous pressure as well as by dilatation of the heart.

Cardiac Response to Increased Aortic Resistance

In similar experiments the venous inflow was maintained constant while the aortic resistance to outflow was increased by tightening the clamp on the aorta. In the subsequent

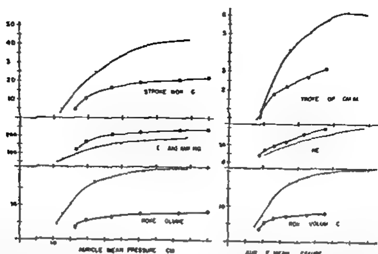

Fig 36 Simultaneously obtained left and right ventricular function curves (Starling curves) in the dog s heart before and during increased aortic resistance Dots indicate control curves Circles indicate curves when screw-clamp increased aortic resistance (From Sarnoff S J and Berglund E Circulation vol 9 1954)

cardiac contraction the left ventricle ejected less blood than formerly (i e less than it received) The remainder was added to the constant venous inflow in diastole The diastolic volume was thus increased Pressure curves of the left ventricle showed an elevation of initial tension and there was an increased force of contraction The heart s output became larger until it ejected as much blood as it received (i e the output returned to its original level) and equilibrium was restored The cardiac output could be thus maintained even when the arterial resistance (pressure) was more than doubled

Thus either an increased venous inflow or an increased resistance to cardiac outflow results first in an increased intracardiac tension and *volume in diastole and then in an increased* force of contraction [53, 54] Consequently despite the greater work imposed by these factors the heart either increases or maintains its output Studies of the respiratory metabolism of the heart revealed that the increased force of contraction following enlargement of the diastolic volume was associated with the liberation of greater chemical as well as mechanical energy [15, 60] *The observation that within physiologic limits a larger diastolic cardiac volume results in a greater energy of contraction and a greater amount of chemical change at each contraction has been termed the Law of the Heart (Starling)* [59] It is the fundamental principle governing the adaptability of the heart in coping with an increased venous inflow of blood to the heart or an increased resistance to its outflow Its validity in the presence of an intact circulation has been both questioned[4, 6, 57] and extended [55]

Starling Curves

However with increasing inflow and increasing diastolic volume the crest of augmented cardiac output is reached and passed Further increments in venous return overload the heart and diminish the cardiac output As the physiologic fitness of the heart muscle is impaired the point of overloading is reached earlier i e with smaller quantities of venous return The reduction in cardiac output relative to filling pressure with greatly increased venous inflow is commonly designated as the descending limb of the Starling curve *Recent studies in the dog with continuous registration of cardiac output and atrial and arterial pressures have confirmed the occurrence of a descending limb when myocardial function is compromised but not in the normal heart with intact pericardium [55] Furthermore it has been suggested that there is not one but a family of Starling curves for a given heart indicating differences in ventricular performance when certain work conditions are altered e g a change in myocardial contractility coronary artery constriction or increased aortic resistance[55] (Fig 36) It has been found that hemodynamic factors such as work load and heart rate affect the mechanical properties of the ventricle[10b, 53] and its oxygen consumption [10a]

Oxygen Consumption and Mechanical Efficiency

The respiratory metabolism of the heart has also been studied in vivo by the technique of catheterization of the coronary sinus. The coronary blood flow which drains into the coronary sinus is estimated by a modification of the nitrous oxide method for measuring cerebral blood flow[11, 5] The oxygen consumption is determined from this value and from simultaneous measurements of the oxygen concentration of coronary sinus blood and of blood from any systemic artery. Since coronary sinus blood does not represent true coronary mixed venous blood but essentially (although perhaps not entirely or exclusively) blood draining the left ventricle the calculated oxygen consumption is relatively accurate only when computed in terms of 100 gm of left ventricular muscle. For total left ventricular oxygen consumption it is necessary to estimate left ventricular weight. While calculations of left ventricular weight may be reasonably accurate in non hypertrophied hearts such calculations in hypertrophied hearts are subject to great error.

The data on myocardial oxygen consumption in vivo obtained by this method have been interpreted as not conforming with the Law of the Heart which is based on observations with the heart lung preparation[7] Left ventricular hypertrophy without failure was found to be associated with a normal oxygen consumption per 100 gm of muscle although increased oxygen consumption might be anticipated from the Law of the Heart. However the latter clearly refers to an increased oxygen consumption with increased diastolic volume only if the physical fitness of the fiber is unaltered as is the case during brief acute experiments. The oxygen consumption in cardiac hypertrophy cannot be compared with that of non hypertrophied fibers in an attempt to apply the Law of the Heart because the fibers are altered in structure and presumably modified in physical fitness. Furthermore since the weight of each hypertrophied fiber is increased and the number of fibers is unchanged a normal oxygen consumption per 100 gm of hypertrophied left ventricle actually denotes an increased oxygen consumption per hypertrophied fiber. This would tend to accord with Starling's Law of the Heart.

Similarly the observed normal oxygen consumption per 100 gm of failing myocardium[8] appears contradictory in view of an anticipated increased oxygen consumption because of the enlarged diastolic volume. But here too the physical fitness of the failing myocardial fibers has been altered and the Law of the Heart cannot be applied if comparison is made with normal myocardial fibers. Furthermore as the heart in failure is an hypertrophied heart a normal oxygen consumption per 100 gm of failing left ventricle actually represents an increased oxygen consumption per failing myocardial fiber. With moderate exercise the size of the heart has been observed to diminish slightly. Accordingly less oxygen utilization might be anticipated according to the Law of the Heart but Lombardo et al[44] actually determined that there was an increase in oxygen consumption according to the technique of coronary sinus catheterization and the nitrous oxide method. Bing Falholt and associates[7] concluded that an increase in initial length of the heart muscle fiber augmented oxidative myocardial metabolism only in the absence of chronic heart failure and that heart failure was accompanied by a defective conversion of oxidative energy into useful work. There is evidence suggesting that during exercise as well as in certain pathologic states nervous humoral or other factors increase the mechanical efficiency or the contractility of the heart muscle without an increase in the length of the muscle fiber or in the oxygen consumption[6, 49] Heart failure is characterized by a reduction in mechanical efficiency the total energy liberation as measured by oxygen consumption being maintained while the mechanical work performed is diminished[48]

ADAPTABILITY OF THE HEART

Cardiac Reserve

Normal cardiac function is characterized by a variability of performance which is remarkably adapted to changing demands. Thus the work of the heart may be increased six fold during exercise and its maximal output during running has been calculated as eight to ten times that of the resting state. The increased needs of the tissues for blood due to various other physiologic functions or pathologic states are satisfied by a corresponding enhancement of the cardiac output. Thus in health and disease the heart is potentially capable of a wide range of increased work

performance beyond that required under basal conditions. The extent of this potentiality is known as the *cardiac reserve*. A reduction in cardiac reserve is the first step on the pathway to cardiac failure. The severity of cardiac disability is measured by the degree of impairment of the cardiac reserve.

The cardiac reserve is related in part to Starling's Law of the Heart. The greater energy of cardiac contraction accompanying an increased diastolic volume is analogous to the more forceful contraction of a strip of skeletal muscle the greater the initial load, i.e., its initial length.[3] Although the force of cardiac contraction has been related to the initial tension by some observers,[19, 61, 15] the weight of evidence supports Starling's conclusion that it is dependent on the initial length of the myocardial fibers.[3] According to the latter concept, increased length of the fibers is associated with a more forceful contraction because of the greater surface area available for chemical activity. This increased energy response with increased initial fiber length may be a fundamental property of the contracting muscle protein, actomyosin.[65] The reserve of the heart is due to the reserve of the individual fibers and the latter in turn depends on their potential ability to undergo an increase in length. Up to a physiologic limit this is accompanied by greater chemical and mechanical energy. Beyond this increased length is accompanied by a diminution in the force of contraction.

Clinically, the cardiac reserve may be theorized as being the difference between the length of the cardiac fibers at rest and their length when the physiologic limit of stretch is reached. If as a result of cardiac disease the cardiac fibers are so elongated that they approach their physiologic limit when the individual is at rest, the cardiac reserve is diminished to virtually zero and the heart may be unable to adapt itself adequately to the increased demands of physical exertion or other physiologic or pathologic strains.

Cardiac Tonus or Tone

There is considerable confusion in the definition and usage of the term "tone" or "tonus," as applied to the heart. Meek[50] has reviewed the evidence which indicates that cardiac tonus in the physiologic sense of a "sustained partial contraction" in diastole does not exist. Tonus has been defined as the degree of resistance to deformation, which according to Kabat and Visscher[34] represents the elasticity of the heart muscle. A diminution in elasticity is correlated with decrease in the external work of the heart and eventually with cardiac failure.

Clinicians often employ the term "cardiac tone" in an ill defined manner to indicate the quality of cardiac contraction. In this sense it is erroneously supposed that the more enlarged the heart, the poorer the tone. The tone of the heart muscle is also supposed to be indicated by the quality of the cardiac sounds. A useful concept of cardiac tone is that proposed by Starling,[69] i.e., the physiologic fitness or mechanical efficiency of the muscle fiber. Thus in the heart lung preparation, when the heart deteriorates after several hours its fibers must have a greater initial length to do the same work that it did when it was fresh. The tone or mechanical efficiency of the muscle fiber is said to be diminished. A heart with good muscular tone may undergo only a slight increase in diastolic volume in order to overcome an elevated arterial resistance, while a diseased heart with poorer tone ("physiologic fitness") may have to dilate much more to accomplish the same work. Starling's Law of the Heart[59] may still apply to the fatigued heart in that a greater diastolic volume results in a greater energy of contraction. But the poorer the cardiac tone the smaller the increment in mechanical work effected by each unit increase in length of the cardiac fibers. Failure of the heart is thus characterized by a decreased capacity for doing work at a given fiber length or at a given diastolic volume.

Reflex Control of Cardiac Output

According to Starling's Law of the Heart the strength of ventricular contraction and the size of cardiac output are determined rather passively by changes in diastolic volume and the consequent degree of stretch of the myocardial fibers. Stead and Warren[62] documented evidence to the effect that the ventricles are actively concerned in determining cardiac output. The cardiac output was found to be independent of wide variations in atrial pressure. A reduction in arterial pressure induced an immediate rise in cardiac output which appeared too rapidly for a humoral mechanism. They suggested that afferent stimuli arising from a reduction in arterial pressure, movement of the limbs during exercise or emotional thoughts produced a

reflex stimulation of cardiac output according to variations in activity and needs. But the possibility is not excluded that such reflexes vary cardiac output not by direct modification of ventricular contraction but by first altering the venous inflow. Factors which reduce the peripheral resistance and thereby increase the speed of circulation ultimately augment cardiac output by enhancing the venous return to the heart. Increase in heart rate without elevation of the stroke output may increase the cardiac output per minute without enlarging the diastolic volume. Factors which improve the physical fitness or mechanical efficiency of the myocardial fibers can evoke an increased stroke and minute output without increasing diastolic volume. There is evidence also that in the *intact animal* the blood pressures in the aorta and in the pulmonary arteries, the autonomic nerves, and hormones such as epinephrine and norepinephrine affect the contractility of the heart and regulate cardiac performance in the same sense as the initial length of the cardiac fibers (end-diastolic volume).[37]

Factors Impairing Cardiac Output

An inadequate cardiac output may result from (1) a deficient venous return, (2) impaired cardiac contraction, (3) increased resistance to cardiac outflow.

1. Except momentarily, the output of the heart is equal to the venous return to the heart. Any reduction in venous return is rapidly mirrored in a corresponding reduction in cardiac output. The venous return may be gauged essentially by the amount of the circulating blood volume and by the speed with which this returns to the heart. Reductions in venous return usually follow a loss of circulating blood volume due to hemorrhage, loss of plasma or severe dehydration, or the venous return may be curtailed by mechanical obstructions to cardiac inflow. Occasionally the venous return falls to a completely inadequate amount following prolonged standing or in some individuals following a change from the recumbent to the erect position. This is due to a pooling of blood in the lower portions of the body because of a failure of sympathetic vasoconstrictor or other mechanisms to maintain an adequate venous return to the heart against the force of gravity. Not only the output of the heart as a whole but the output of each of its chambers is conditioned by the quantity of blood which is brought to it. Therefore the inflow of blood and the output from the right or left ventricle tend to be diminished if there is an obstruction or stenosis of the tricuspid or mitral valves respectively.

2. Impaired cardiac contraction or a diminution in its physiologic fitness accounts for the great majority of instances of inadequate cardiac output and therefore of cardiac insufficiency. This is usually the result of a deficient blood supply (coronary insufficiency) or of diseases which damage the heart muscle or impair its physiologic efficiency. As we shall see, the *normal* cardiac muscle can long compensate for many serious loads imposed by cardiovascular or other diseases and still accommodate to the strains of vigorous activities. But with a reduction in myocardial strength and efficiency, overloading of the heart and inadequacy of output occur with progressively smaller stresses.

3. Increased resistance to outflow tends to reduce the cardiac output from the atria into the ventricles if there is an atrioventricular valvular stenosis, or from the ventricles into the great vessels if there is an aortic or pulmonic valvular stenosis. Hypertension with its increased peripheral resistance tends to reduce the output of the left ventricle.

Other factors which tend to reduce the cardiac output and thereby provoke heart failure include the valvular insufficiencies which cause a regurgitation of some of the expelled blood. Thereby the effective blood flow to the tissues is less than the original ventricular output by the amount regurgitated. Similarly in shunts between large arteries and veins or between the right and left sides of the heart, the actual blood flow to the tissues is diminished by the quantity of shunted blood.

Finally the output may be inadequate in relation to inordinate requirements of the tissues because of excessive metabolism, e.g., hyperthyroidism, or because the normal quantity of blood is deficient in hemoglobin (anemias), vitamins (beriberi), or oxygen (advanced pulmonary emphysema). In the latter circumstances adequate amounts of oxygen, vitamins, etc., can be provided only by augmented cardiac outputs. In many cases inadequacy of cardiac output is the result of a combination of factors, e.g., an increased demand of the tissues plus myocardial impairment in cases of anemia, or increased resistance to outflow plus myocardial

damage in cases of hypertension with advanced coronary atherosclerosis

The following sections are concerned with the compensatory mechanisms by which the heart and circulation long maintain an adequate output despite these factors

CARDIAC AND CIRCULATORY COMPENSATIONS

Compensation and Decompensation

A number of cardiac and circulatory compensations serve to restore an adequate output whenever the latter is threatened by disease *When these adjustments succeed in maintaining an adequate blood flow without distressing symptoms the heart and circulation are said to be in a state of compensation*

Compensation may be complete or incomplete Compensation is complete when the strain of the disease has been overcome, yet sufficient cardiac reserve remains to meet adequately the diverse demands of an active physical life Incomplete compensation or cardiac decompensation denotes a substantial expenditure of the cardiac reserve in order to overcome the load imposed by disease, the remainder is such that unpleasant symptoms develop with slight or moderate activity When the heart is adjusted to the disease factor but has no reserve for physical exertion the heart is said to be compensated only at rest

Types of Cardiac and Circulatory Adjustments

1 The primary compensations concern the heart directly and include tachycardia cardiac dilatation and cardiac hypertrophy

2 When these primary compensations fail to restore or maintain an adequate cardiac output renal retention of sodium and water tends to increase the blood volume and thereby the venous return (Chapter 8) Within certain limits this tends to restore an adequate cardiac output

3 *If the reduction in cardiac output is severe* and occurs very rapidly (within a few hours) a significant augmentation of blood volume and venous return cannot be effected Instead the deficient output is reapportioned so as to divert its major fraction to the vital brain and heart (Chapter 12)

4 A deficiency in cardiac output may be compensated also by metabolic hematologic and other adjustments e g an increase in erythrocytes in cases of congenital heart disease or chronic pulmonary disease, or increased extraction or utilization of the oxygen available in the transported blood Other cardiac factors of safety have been enumerated by Alexander and Wiggers [2]

CARDIAC COMPENSATION BY TACHYCARDIA

The cardiac output (minute volume of blood flow) is equal to the product of the stroke output and the cardiac rate *When the* cardiac output must be augmented to accommodate increased tissue demands due to exercise this is accomplished by both an increase in rate and an increase in output Of the two, the acceleration in rate is the less efficient mechanism In the heart lung preparation studied by Starling and Visscher it was found that a given unit of work was performed more efficiently i e with a lesser consumption of oxygen the slower the cardiac rate [60] In athletes and subjects who have undergone a period of training a physiologic enhancement of minute volume is accomplished essentially by an increased output per beat and to a lesser extent by an increased cardiac rate [12]

Similarly when the cardiac output is inadequate because of disease, it can be increased and restored to normal levels either by tachycardia or by augmented stroke output As a rule tachycardia appears only as a transient compensatory mechanism especially with sudden increases in cardiac demands More efficient and more permanent compensation results from cardiac dilatation and hypertrophy which augment the total output by increasing the output per beat

An accelerated heart rate (tachycardia) appears not only as a compensation for an inadequate cardiac output but also as a result of a variety of unrelated conditions When a deficient output is compensated by dilatation and hypertrophy the heart rate is usually normal However muscular exercise in the subject with cardiac dilatation and hypertrophy often induces a greater acceleration of the heart rate and greater persistence of such tachycardia at the conclusion of activity than is found in the normal person When the cardiac output is uncompensated despite cardiac dilatation hypertrophy and other mechanisms (i e in heart failure) tachycardia is often present despite minimal activity Tachycardia is the major cardiac compensation when the stroke output cannot be increased either because of severe acute

myocardial injury or because of a sharply reduced blood volume and venous inflow into the heart (shock)

The compensatory value of tachycardia is limited by the shortening of diastole and consequent reduction in ventricular filling as the rate increases Experiments with the heart lung preparation have shown that beyond the rate of 180 beats per minute the reduction in ventricular filling and ventricular output becomes so great that further increases in cardiac rate actually reduce the total minute volume [8]

Pathogenesis of Compensatory Tachycardia

A compensatory increase in heart rate is effected by various mechanical chemical and nervous stimuli which diminish the tone of the cardioinhibitory center and vagus nerve and increase that of the cardioaccelerator centers and accelerator fibers in the sympathetic nerves [illegible] A fall in aortic and carotid arterial pressure as the cardiac output is reduced inhibits the carotid sinus and aortic depressor nerves and reflexly reduces vagal tone [27, 31, illegible] At the same time an inadequate output tends to be associated with stasis and elevation of pressure in the vena cava and right atrium This may stimulate receptors which reflexly cause cardiac acceleration by inhibiting the vagus and stimulating the accelerator center and fibers (Bainbridge reflex) [5] (The site and significance of this reflex have been amplified by Nonidez[31] and questioned by DeGraff and Sands[13] and by Anrep and Segall [4]) The secretion of epinephrine and the accumulation of metabolites as the output falls may also be concerned in effecting a compensatory tachycardia The exact mechanisms are uncertain

CARDIAC DILATATION

Cardiac dilatation denotes an increased capacity of the cardiac chambers Its compensatory action is explained by the Law of the Heart (p 85) Since the length of the muscle fiber determines the mechanical energy set free ' or the strength of contraction dilatation of the heart by elongating myocardial fibers results in more work and an increased stroke output The greater effectiveness is probably due to the larger surface area of elongated fibers available for active physicochemical processes The extent of cardiac dilatation necessary to compensate a given load due to cardiovascular disease increases as the load increases or as the physiologic fitness of the myocardium diminishes On the one hand the dilated myocardium possesses the advantage of greater work performance according to Starling's Law as well as a lesser degree of shortening per muscle fiber to eject a given volume of blood during systole than is required in the normal heart [11] On the other hand the dilated heart must support a greater load and expend a greater amount of energy to attain the same cardiac output

Cardiac enlargement chiefly due to dilatation of its chambers is the commonest manifestation of any cardiovascular disease which tends to impair the cardiac output Furthermore the dilatation is localized or most conspicuous in that cardiac chamber or even in that portion of a chamber, which is subjected to the greatest strain The frequent observation that individuals with cardiac enlargement are long able to maintain good circulatory function, supports the concept that cardiac dilatation is a mechanism for compensating cardiovascular lesions which tend to interfere with an adequate cardiac output

Cardiovascular Diseases and Compensatory Dilatation

Cardiac dilatation may result from (1) mechanical lesions (2) myocardial lesions or often a combination of both

1 *Mechanical lesions* tend to increase the diastolic volume and thereby cause cardiac dilatation by (a) increasing the venous return to the heart e g in cases of arteriovenous aneurysm (b) increasing the resistance to outflow from one of its chambers e g mitral or aortic valvular stenosis or hypertension (c) permitting a reflux of blood into a chamber after it is ejected, e g in aortic valvular insufficiency

2 *Myocardial lesions* tend to impair cardiac contraction and diminish cardiac output while the inflow is temporarily unchanged This causes an increase in the diastolic volume and cardiac dilatation (e g myocardial infarcts secondary to coronary occlusions rheumatic myocarditis etc) However the experimental destruction by cautery of 75 to 95 per cent of the free wall of the right ventricle of the dog is not followed by any significant rise in venous pressure or alteration in pulmonary artery pressures [61, illegible] The mechanism of compensation and maintenance of right ventricular output is uncertain [illegible]

Most frequently cardiac contraction is im

paired by coronary artery disease or rheumatic myocarditis at the same time that a mechanical strain is imposed by hypertension or valvular defects. Whether due to a mechanical lesion or to an impaired myocardial contraction, dilatation results from an inability of the affected chamber to expel an increased venous return or to eject a normal venous return against an abnormal obstruction or a regurgitant stream.

The normal ventricle does not empty itself completely during systole but leaves a *residual volume* which, in the case of the right ventricle, varies from 25 to 160 cc but averages about 50 cc per square meter of body surface area.[30, 9, 45] The end diastolic volume, or volume of blood in the ventricular cavity during isometric contraction, determines the stretch on the myocardial fibers and therefore influences the strength of contraction. It is equal to the sum of the stroke output plus the residual volume. In heart failure the diastolic volume, the residual volume and the ratio of the residual to the stroke volume are increased.

When heart failure occurs, the compensatory mechanisms may be said to have failed in restoring an adequate cardiac output. However, they continue to operate. If a moderate degree of cardiac dilatation effects the needed increase in cardiac output, this remains unchanged so long as the status of the myocardium and the mechanical lesion remain unchanged. If the cardiac output is definitely inadequate despite a given degree of dilatation (i.e., cardiac failure ensues), the heart continues to dilate in a futile compensatory effort. The enlarged circulating blood volume which is an essential feature of chronic heart failure contributes significantly to the increased diastolic volume and cardiac dilatation. Thus the most rapid and pronounced degrees of cardiac enlargement are observed in the failing heart.

CARDIAC HYPERTROPHY

Cardiac hypertrophy denotes an increase in the weight of the heart associated with an enlargement of the individual muscle fibers. Pseudohypertrophy and false hypertrophy are terms that have been applied to hearts whose weights are increased not by enlargement of muscle fibers but by edema as in beriberi, or by glycogen infiltration. It had been generally accepted that cardiac hypertrophy is associated with an increase in the diameter and volume of the individual fibers but with no increase in their number.[26] But studies by Linzbach suggest that this may apply only to hearts which are hypertrophied to a total weight of 500 gm. Beyond that point the thickened hypertrophied fibers may split longitudinally and produce an increase in the number of fibers.[44]

Cardiac hypertrophy may sometimes be surmised from clinical and roentgenologic studies, especially angiocardiography, but essentially it is a postmortem diagnosis based on the weight of the heart, the thickness of chamber walls or gross and histologic examination. Hypertrophy of individual chambers may be similarly determined by dissection and by weighing.[8, 41, 1] Normally the heart weighs 0.43 per cent of the body weight in men, 0.40 per cent in women.[illegible] The heart weight is directly proportional to muscular development and therefore in obese individuals the percentage of heart to body weight is less than in muscular persons. A heart weighing *more than 400 gm. in an adult male* or more than 375 gm. in an adult female [illegible] practically always hypertrophied. [illegible] rule weights exceeding 350 gm. and 300 gm. respectively denote cardiac hypertrophy. At birth the percentage of heart weight to body weight averages 0.62 per cent for males and 0.55 per cent for females. In old age there is usually *some atrophy of the heart*.

According to Fulton and coworkers[21] the normal total ventricular weight is less than 250 gm., the free wall of the right ventricle weighs less than 65 gm. and the combined weight of the left ventricle and ventricular septum is less than 190 gm. The left ventricle is regarded as hypertrophied if, together with the septum, it weighs 225 gm. or more. Right ventricular hypertrophy is indicated if the free wall of the right ventricle weighs 80 gm. or more or if the ratio of its weight to that of the combined weight of the left ventricle and septum is greater than 1:2. In hearts with isolated right ventricular hypertrophy, the total ventricular weight may fall within normal limits. The normal thickness of the left ventricle midway between apex and mitral valve is 10 to 12 mm., that of the right ventricle midway between apex and pulmonary valve is 3 to 4 mm.

The determination of dilatation and hypertrophy of individual segments of the various

chambers at necropsy examination has been described by Kirch.[89]

The Compensatory Nature of Cardiac Hypertrophy

That cardiac hypertrophy is a compensatory mechanism is concluded from the experimental pathologic and clinical observations that (1) it appears when there is a disturbance which tends to interfere with normal cardiac function, (2) it is localized in the chamber or chambers affected by the disturbance, (3) after its development normal cardiac function is frequently restored.

Experimental evidence indicates that the hypertrophied heart not only maintains the normal circulation despite a cardiovascular lesion but also retains an adequate reserve for unusual circulatory demand. Hasenfeld and Romberg[4] produced aortic insufficiency in rabbits hearts and observed the development of cardiac hypertrophy. They concluded that the reserve strength of the heart was not impaired and that cardiac hypertrophy is a sign of increased strength. Similarly Wolfer[3] observed that rabbits hearts which had become hypertrophied after experimentally produced aortic stenosis or repeated injection of epinephrine responded perfectly to increased physical demands. Dieckhoff[14] actually found that in acute experiments the experimentally hypertrophied heart displayed an increased capacity for work when compared to the normal heart.

From clinical and pathologic studies it is clear that cardiac hypertrophy is not incompatible either with normal activity or with long life. I have observed individuals who in spite of their enormous hearts associated with aortic stenosis or insufficiency have engaged in the severest athletics and lived a normal span of life. For practical purposes no distinction could be made between the physical capabilities of these individuals and those of persons with normal hearts.

There are many unanswered questions regarding the nature dynamic properties and pathogenesis of cardiac hypertrophy. The concept that the hypertrophied myocardial fiber is stronger than the normal fiber or that it imparts greater strength of contraction to cardiac muscle has been questioned.[4]

Relation of Cardiac Dilatation and Cardiac Hypertrophy

Cardiac hypertrophy and cardiac dilatation are both compensatory mechanisms. Cardiac dilatation appears to be the immediate response of the heart when it must expel a constant or increased volume of blood against an increased resistance or an increased volume against a constant resistance. While the dilated heart overcomes these obstacles it does so with less mechanical efficiency than the normal heart and by encroaching on the cardiac reserve. It may be that cardiac hypertrophy is a more efficient long term compensatory response to similar cardiovascular disturbances but it requires more time to develop.[34]

Experimental and pathologic evidence indicates that cardiac dilatation and hypertrophy are responses to the same stimuli dilatation occurring immediately and hypertrophy after some time and probably as a result of unknown physicochemical changes induced by the primary dilatation. The lengthening of muscle fibers associated with cardiac dilatation allows a greater surface area for the diffusion of metabolites which may aid in the growth of the fibers. Horvath[33] first emphasized that the development of cardiac hypertrophy was dependent on and preceded by cardiac dilatation. Eyster Meek and Hodges[17] showed that following experimental aortic insufficiency and aortic stenosis in dogs dilatation occurred rapidly and reached a maximum in three to six days. Hypertrophy developed subsequently and was maximal only after one hundred days.

In human pathology cardiac dilatation and hypertrophy are almost always associated and localized in the same portions of the heart. This indicates that they are responses to the same stimulus. Sometimes it can be demonstrated that dilatation precedes hypertrophy. Thus in cases of acute glomerulonephritis death from cardiac failure occasionally occurs in the first week of the illness. The hearts show definite dilatation but no hypertrophy. On the other hand if death occurs after a month a significant degree of hypertrophy is present.

Pathogenesis of Cardiac Hypertrophy

Many theories have been proposed to explain the development of cardiac hypertrophy.[65, 29]

1 *The theory of work hypertrophy* imputes cardiac hypertrophy to an increase in the work of the heart. Observations in animals indicate that the size of an animal s heart increases in proportion to the amount of activity necessi

tated by its mode of life and that cardiac hypertrophy can be induced by exercising dogs[42] Clinical and pathologic observations disclose that hypertrophy of a chamber occurs when its work is increased in compensation for a valvular or circulatory abnormality

2 *The nutritional theory* attributes cardiac hypertrophy to a defective blood supply and is based largely on the development of hypertrophy in clinical and experimental anemia and the belief that cardiac hypertrophy in arteriovenous aneurysm and aortic insufficiency is due to a deficient coronary circulation[4]

3 *The injury theory* suggests that cardiac hypertrophy is a reaction to tissue injury which acts as a pathologic nutritive stimulus[1, 17]

4 *The muscular stretch theory* suggests that the fundamental cause of hypertrophy is the stretching of muscle fibers[23] This is not necessarily contradictory to the above theories but more clearly and precisely defines their application Stretching of myocardial fibers results whenever the diastolic volume and pressure are increased by enhanced inflow impaired myocardial contraction or increased resistance to outflow This is the stage of cardiac dilatation

The lengthening of muscle fibers results in a greater surface area for an unchanged mass of muscle This permits a relatively greater nutritive diffusion surface between blood and fiber and therefore leads to the fiber's growth In due time the dilated fibers become hypertrophied This explains the development of cardiac hypertrophy following dilatation in cases of valvular and vascular lesions as well as in instances of myocardial disease Hormonal factors especially the growth hormone may be concerned in the development of cardiac hypertrophy [8] Progressive heart failure is a potent factor in pronounced cardiac hypertrophy because it is responsible for a progressive increase in diastolic volume and consequent muscle stretch On the other hand, increased work of the heart does not cause hypertrophy if the additional work is due exclusively to tachycardia while the stroke output is not enhanced, as in most cases of uncomplicated hyperthyroidism Finally, there are many unknown extrinsic or intrinsic factors controlling the metabolism of the muscle fiber which may account for the marked difference in the degree of hypertrophy experienced by different hearts in response to apparently similar pathologic disturbances Hearts in aortic stenosis have varied from virtually normal weight to over 2000 gm,[48] sometimes without quantitative correlation to the degree of stenosis or duration of illness Although marked hypertrophy is the rule in cases of hypertension with heart failure little or no hypertrophy has been found at autopsy in the hearts of some patients with these conditions[49]

Reversibility of Cardiac Dilatation and Hypertrophy

Roentgenologic observations have disclosed that cardiac enlargement (dilatation and hypertrophy) is reversible even when it has been present for years provided that the causative disturbance is abolished or alleviated[46] Cardiac enlargement has been seen to diminish with regression of the symptoms of heart failure and to disappear completely or diminish with (a) subsidence of acute glomerulonephritis (b) correction of anemia, (c) surgical correction of an arteriovenous aneurysm patent ductus arteriosus coarctation of aorta or hyperthyroidism with heart failure (d) adequate thyroid administration in myxedema heart disease (e) vitamin B and protein therapy in beriberi heart disease (f) sympathectomy in hypertensive heart disease

That cardiac hypertrophy as well as dilatation is reversible is indicated by the case of arteriovenous aneurysm due to congenital cavernous hemangioma reported by Matas and Heninger[47] The greatly enlarged heart in this case was restored to normal size as determined roentgenologically following surgical removal of the hemangioma Because cardiac enlargement had been present at least four years Matas and Heninger believed there must have been hypertrophy as well as dilatation and that hypertrophy like dilatation could regress when the cause was removed Electrocardiographic and roentgen ray studies of the heart in hypertensive heart disease before and after sympathectomy also indicate that ventricular hypertrophy is reversible (p 949)

CIRCULATORY COMPENSATION BY INCREASED BLOOD VOLUME AND VENOUS RETURN

When cardiac dilatation and hypertrophy with or without tachycardia are no longer capable of maintaining an adequate cardiac

output the cardiac reserve is largely expended and there is an insufficient blood supply to the tissues. This deficiency in blood flow may occur only with physical exertion or in extreme cases even with the patient at rest. At this stage extracardiac compensatory mechanisms are invoked and these may partially or completely restore the cardiac output for a variable period.

Briefly a diminished cardiac output causes a deficient blood flow to the kidneys and other organs and tissues which in some manner results in a retention of sodium and water and a corresponding increase in the circulating blood volume. The latter augments the venous return and thereby stimulates the failing ventricle to restore an adequate output according to the Law of the Heart. This compensatory mechanism will be discussed in detail in the chapter on the pathogenesis of congestive heart failure (Chapter 8).

CIRCULATORY COMPENSATION BY REDISTRIBUTION OF A DIMINISHED CARDIAC OUTPUT

A significant compensatory increase in blood volume can be effected only over a period of days or weeks. Furthermore this compensatory mechanism is most effective when the reduction in cardiac output is relatively small (10 to 30 per cent). When a diminution in cardiac output occurs rapidly (in a few hours) and is of pronounced degree (35 per cent or more) a restoration of cardiac output cannot be rapidly accomplished by an increased blood volume or by any other means. A slight immediate compensatory increase in circulating blood volume may occur as a result of an intravascular influx of extracellular or intracellular fluid but this is clinically insignificant.

To preserve the life of vital organs such as the brain and heart the little blood flow available is redistributed in such a way as to divert most of it from the periphery and splanchnic areas to more vital structures. This is probably accomplished in large measure by reflex inhibition of carotid sinus and aortic depressor tone, by promoting the secretion of norepinephrine and perhaps by direct anoxemic stimulation of the vasomotor center—all of which produce sympathetic vasoconstriction especially of the skin and splanchnic viscera. This compensatory mechanism is discussed more fully in the section on the pathogenesis of acute circulatory failure or shock (Chapter 12). Vasoconstrictive redistribution of blood also occurs in the more chronic and milder forms of deficient cardiac output, but it is less important than the mechanism of increased blood volume.

Relation of Compensatory Mechanisms to Clinical Manifestations of Cardiac and Circulatory Dysfunction

Except in occasional instances of extreme and acute reduction of cardiac output, symptoms of circulatory deficiency are not due directly to the inadequate output. In cases of irreversible and fatal shock, syncope and sudden death the compensatory mechanisms have failed to maintain an adequate output to supply vital organs notably the brain; temporary unconsciousness or death is actually due to the deficient output. As a rule however despite serious cardiovascular disease the blood flow to the brain and heart is adequately maintained by the enumerated compensations. Under these circumstances the clinical manifestations of the cardiovascular diseases which have threatened the adequacy of the circulation are determined not by insufficient output but by the compensations which restore that output.

In the mildest cases a falling cardiac output is adjusted by cardiac dilatation and hypertrophy which are denoted clinically by signs of enlargement of the heart. The patient is said to have compensated heart disease. The compensations (cardiac dilatation and hypertrophy) are the evidence of cardiovascular disease. Although beneficent in their effect on cardiac output they are abnormal in that they denote the existence of a serious disease which requires cardiac compensation and in that they expend some of the reserve power of the heart. Furthermore the enlarged hypertrophied heart has increased muscle mass without a corresponding increase in the number or size of the blood vessels. This disparity predisposes to myocardial inefficiency and heart failure (p. 128). Thus cardiac enlargement may be considered as a compensatory process (Chapter 4), as an evidence of cardiovascular disease (Chapter 5) and as a mechanism predisposing to heart failure (Chapter 6).

When extracardiac compensations must be invoked to maintain an adequate cardiac output, clinical evidence of cardiac or circulatory failure appears. Here also the clinical manifestations are not entirely the direct result of a deficient cardiac output but also of the

compensatory mechanisms which attempt to restore that output Since heart failure or circulatory failure is defined in terms of clinical phenomena and these are produced by circulatory compensations as well as by deficient output heart failure may be present despite an adequate output The deficient output initiates the compensatory mechanism but the compensatory mechanism produces symptoms

When the extracardiac compensation is chiefly that of increased circulating blood volume, the resulting clinical phenomena are those of chronic circulatory or cardiac failure When the extracardiac compensation is chiefly that of redistribution of a greatly diminished output the compensatory process leads to the clinical phenomena known as acute circulatory failure (shock) Syncope and death are often manifestations of acute circulatory failure and are actually due to the deficient output itself in such instances the compensation of redistribution of blood to the vital brain has failed temporarily or permanently

Accordingly the following classification of circulatory failure is proposed

CLASSIFICATION OF CIRCULATORY FAILURE

I—Chronic circulatory failure (congestive heart failure)
- A—Left-sided heart failure
- B—Right-sided heart failure
- C—Combined left and right sided failure
- D—Heart failure due to prolonged or chronic *interference with inflow*
  1. Constrictive pericarditis
  2. Persistent severe tachycardias
- E—Heart failure associated with increased *venous return (high output failure)*
  1. Arteriovenous aneurysm
  2. Chronic severe anemias
  3. Beriberi
  4. Hyperthyroidism
  5. Pulmonary emphysema
  6. Paget s disease

II—Acute circulatory failure (Chapter 12)
- A—Shock
- B—Syncope
- C—Sudden death

Chapter 5

ENLARGEMENT OF THE HEART

This chapter is concerned with cardiac dilatation and hypertrophy not as compensatory mechanisms but as evidences of myocardial valvular or circulatory disease In clinical discussions the term cardiac enlargement is employed to signify dilatation and/or hypertrophy, because the determination of the presence and degree of each of the latter is extremely difficult

Clinical recognition of cardiac enlargement depends chiefly on physical and roentgenologic examination The presence of cardiac enlargement may also be indicated or confirmed by the electrocardiographic findings Cardiac enlargement not only denotes the presence of cardiac disease but also, because of its characteristic localizations may suggest the exact nature of the cardiac lesion

PHYSICAL SIGNS OF CARDIAC ENLARGEMENT

The chief physical signs of cardiac enlargement are displacement of the apex beat as determined by inspection and palpation or displacement of the cardiac borders as determined by percussion As a rule cardiac enlargement is present when the maximum apical impulse is situated lateral to the midclavicular line or more than 10 cm from the midsternal line in the fifth left intercostal space or below the level of the fifth intercostal space Cardiac displacement due to bronchopulmonary lesions may similarly affect the position of the apical impulse In many persons it is difficult or impossible either to see or clearly to feel the apex beat

Cardiac enlargement may also be denoted by an accentuated or diffuse apical impulse The accentuated apical impulse due to hypertrophy of the left ventricle was considered characteristic of aortic insufficiency by Bard [2] who termed the pulsation "choc en dome Enlargement of the right ventricle may be suggested by a pronounced epigastric pulsation A precordial bulge is often observed in children with cardiac enlargement due to rheumatic or congenital cardiac disease Distinctive pulsations of the chest wall have been associated with individual cardiac lesions [15]

Percussion discloses cardiac enlargement or displacement if cardiac dullness extends beyond 10 cm to the left of the midsternal line in the fifth interspace It may denote either left or right ventricular enlargement If cardiac dullness extends more than 4 cm from the midsternal line in the third left interspace, there is probably enlargement of the left atrium dilatation of the pulmonary artery or possibly enlargement of the pulmonary conus of the right ventricle The value of percussion of the right side and base of the heart is more limited except in cases of gross enlargement The accuracy with which cardiac enlargement can be discovered by percussion is impaired in very obese individuals in those with a very muscular chest wall in subjects with pronounced pulmonary emphysema and in women with large breasts Despite the imperfections of these physical methods the physician should refine his skill in them because they are the only means of discovering cardiac enlargement at the bedside when the patient is too ill or facilities are not available for roentgen ray examination

ROENTGENOLOGIC DIAGNOSIS OF CARDIAC ENLARGEMENT

Often single examinations are inconclusive as to the presence of cardiac enlargement But when permanent records are made at intervals, a comparison of these records may reveal significant changes in size indicative of cardiac enlargement

The size of the heart and the presence of generalized or local cardiac enlargement may be determined by fluoroscopy orthodiagraphy

and teleoroentgenography In special instances especially in cases of congenital heart disease and to distinguish cardiac enlargement from an extracardiac mass angiocardiography has proved to be valuable When performed with *simultaneous exposures in* two projections at right angles to each other (p 15) it permits a three-dimensional appreciation of the size and configuration of the cardiac chambers and more accurate assessment of cardiac enlargement Kymography and electrokymography may aid in distinguishing cardiac enlargement from pericardial enlargement and ventricular aneurysm Tomography (planigraphy) has been recommended to distinguish left from right ventricular enlargement a distinction which is both difficult and important in differentiating mitral stenosis from mitral insufficiency

In clinical practice cardiac enlargement is most commonly discovered or verified by fluoroscopy Although this method is largely subjective it is surprisingly accurate when used by one who attains skill with persistent study and experience *Fluoroscopy* is especially useful in recognizing enlargement of individual cardiac chambers, this is aided by rotating the patient so as to obtain multiple views of the cardiac silhouette and by observing the indentation of the heart on the barium filled esophagus

CARDIAC MENSURATION

For more objective determination of cardiac enlargement orthodiagraphs or roentgenographs of the chest at 2 meters distance are used *to measure various dimensions of the* posteroanterior cardiac silhouette[11] (Fig 37) These measurements are then compared with predicted measurements for height weight or surface area and sex as noted in available tables (Fig 38) The determination of cardiac enlargement may be based on calculation of the area of the frontal cardiac silhouette or of the volume of the heart (p 101) but these methods while theoretically more accurate are relatively difficult and rarely used

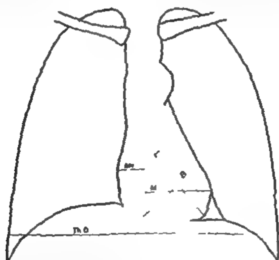

Fig 37 Cardiac diameters of normal heart in Fig 1 Mr = 4 1 cm Ml = 7 3 cm TD (transverse diameter) = Mr + Ml = 11 4 cm Internal thoracic diameter Th D = 30 5 cm L (long diameter) = 13 4 cm B (broad diameter) sum of perpendiculars to L = 10 4 cm

Cardiothoracic Ratio

The cardiothoracic ratio has often been used as an index of cardiac enlargement [12] This is the ratio of the transverse diameter of the heart (p 100) to the internal diameter of the chest at its widest point just above the level of the dome of the diaphragm If the cardiothoracic ratio significantly exceeds 50 per cent it is assumed that there is cardiac enlargement This is *only* a rough guide and is often inaccurate as the relationship between the diameter of the heart and that of the chest varies considerably [10]

The Transverse Diameter

The transverse diameter (p 100) which bears a definite relation to body surface area

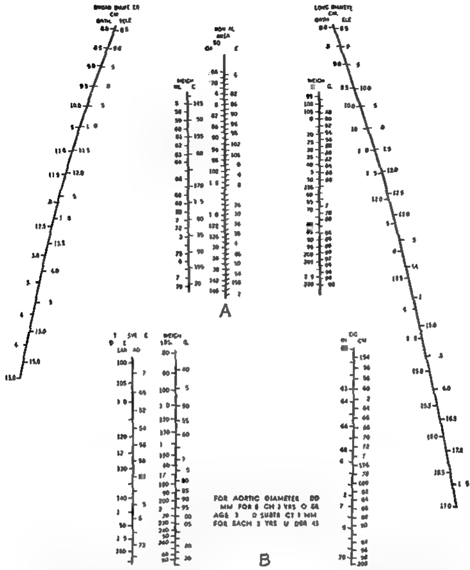

Fig 38 *A* Nomogram for prediction of frontal area of cardiac silhouette and for actual area from long and broad diameters (Ungerleider—Gubner) Extension of line connecting height and weight gives predicted area and connecting long and broad diameters gives actual area

B Prediction table for transverse diameter of cardiac silhouette (Ungerleider—Gubner) The theoretical transverse diameter of the heart (left column) is obtained by extension of line connecting height and weight Actual transverse diameter exceeding predicted value by more than 10 per cent is abnormal

or to height and weight has proved more valuable as an objective criterion of cardiac enlargement The transverse diameter (T or H) is the sum of the perpendicular from the outermost point of the right cardiac border to the midsternal line (MR) and the perpendicular from the outermost point of the left cardiac border to the midsternal line (ML) (Fig 37) In the erect position of the body, the transverse diameter averages between 10 and 13 cm, but even greater variations may occur normally Comparison of the measured transverse diameter of the heart with the prediction table of normal transverse diameter for given heights and weights[82] (Fig 38) gives a relatively accurate indication of cardiac enlargement [70] Similar tables for children have been prepared by Gordon and Adams [26] The tables for adults allow too high values for obese patients and are unsuitable in the presence of chest deformities, ascites or pregnancy When the measured transverse diameter exceeds the predicted value by more than 10 per cent the heart is probably enlarged when it exceeds the predicted value by more than 15 per cent the heart is almost always enlarged [81]

Certain limitations of this method must be recognized Some of the factors modifying the normal cardiac silhouette have been discussed (p 7) A transversely placed heart may suggest left ventricular enlargement In funnel breast with depression of the lower part of the sternum there is a flattening of the heart with apparent transverse enlargement The method of measuring the transverse diameter fails to consider the depth of the heart Thus the heart may be significantly enlarged by volume but not according to the transverse diameter This applies particularly to advanced obstructive emphysema with anteriorly directed enlargement of the right ventricle

The Long and Broad Diameters

Other measurements are employed to determine enlargement of individual portions of the heart The *long diameter* (or oblique diameter) of the heart (L) is the distance from the cardiac apex on the left to the junction of the right atrium with the superior vena cava or ascending aorta on the right The usual range of this dimension in the adult male is between 12 and 15 cm Normally the long diameter is about 1 5 cm or 10 per cent greater than the transverse diameter It is increased chiefly by enlargement of the left ventricle

The *broad diameter of the heart* (B) is the sum of the perpendicular (BR) from the point of junction of the right atrium with the diaphragm to the long diameter and the perpendicular (BL) from the point of junction of the left ventricle with the pulmonary arc to the long diameter The length of the broad diameter ranges between 8 and 11 cm in the adult male The broad diameter ranges between 65 and 85 per cent (average, 75 per cent) of the long diameter If the broad diameter exceeds 85 per cent of the length of the long diameter there is usually definite enlargement of the right ventricle

The Area of the Frontal Cardiac Silhouette

This area in relation to standards based on weight and height has been recommended as a criterion of cardiac size Ungerleider and Gubner[83] used the formula Area $= \frac{3}{4}\pi \times$ long $\times$ broad diameters and found that the calculated values showed a mean deviation of less than 3 per cent from the actual area as measured by planimetry They prepared a nomogram for direct reading without calculation of the frontal area when the broad and long diameters are known as well as for the prediction of the normal area from weight and height (Fig 38) The heart is considered enlarged if its frontal surface area exceeds predicted values by more than 10 per cent

Volume of the Heart

This may be determined most accurately by the actual volumetric reconstruction of the heart as a plastic model whose volume is equal to the amount of water it displaces when immersed The construction of such models has been described by Lysholm[53] Schatzki[66] and by Palmieri[59] The volume of the heart has been determined also from measurements of the area of the cardiac silhouette in the posteroanterior view and from the depth in the lateral view[45, 6] (See also Tomography p 7) Formulae for its calculation, suggested by Rohrer[63] by Kahlstorf[39] and by Jonsell[38] are based on the fact that the form of the heart is between that of an ellipsoid and a paraboloid The volume equals length $\times$ width $\times$ depth $\times$ 0 63 the latter being a constant used because the heart has the configuration mentioned rather than that of a three-dimensional solid Calculated thus the average volume of the heart ranges between 650 and 700 cc for the male and between 500 and 550 cc for the female According to Larsson and Kjellberg[45] the average normal cardiac volume is 785 cc for men 560 cc for women and as much as 1015 cc for athletes In general these calculations of cardiac volume have not proved of practical value in clinical practice

The total cardiac volume is the sum of the muscle volume of the heart plus the volume of blood in the cardiac chambers By determining the total heart volume by calculations as indicated and the volume of blood in the cardiac chambers by dye methods (p 223) the volume of cardiac muscle may be obtained by subtraction[2] The amount of blood in the heart in diastole was found to average 500 cc in males 320 cc in females and 685 cc in athletes Normally the amount of blood in the heart in diastole and the total cardiac volume are proportional to the total blood volume According to Sjostrand[72] in physiologic enlargement of the heart such as may occur in athletes the cardiac volume retains its normal relation to the total circulating blood volume in pathologic enlargement of the heart its volume increases out of proportion to the total blood volume

ENLARGEMENT OF THE INDIVIDUAL CHAMBERS

Cardiac enlargement may involve the entire heart, as in various toxic, infectious and metabolic diseases severe anemias and certain forms of combined left and right sided heart failure But in some of the most frequent and most important forms of cardiac disease especially in their less advanced stages, cardiac enlargement is confined to a single chamber or to two chambers These localized forms of enlargement are characteristic of certain diseases and are therefore of great diagnostic value Kirch[42] showed that enlargement may be confined not only to a single chamber but even to a special portion of that chamber The ventricles may be divided anatomically and physiologically into inflow and outflow tracts the inflow tract being the posterior segment of the ventricle between the atrial ventricular ostium and the apex, and the outflow tract being the anterior segment between the apex and the semilunar valve It is important to note that enlargement of the ventricles begins in the outflow tract first near the arterial ostium and then toward the apex, so that elongation of the chamber occurs Only later, when the inflow tract becomes enlarged is widening of the chamber seen roentgenologically Thus dilatation of a chamber may produce either elongation or widening Since it is more difficult to recognize the former roentgenologically, the earliest stages of cardiac enlargement may be overlooked

Left Ventricle

Early enlargement of the left ventricle begins in the outflow tract, involving the anterior wall and septum near the aorta Since this region is not part of the cardiac border in the dorsoventral silhouette it is not easily noted roentgenoscopically Moderate left ventricular hypertrophy with minimal dilatation (so called concentric hypertrophy) as seen in essential hypertension, may be characterized by moderate rounding of the left lower contour without significant alteration in cardiac diameters (Fig 39) An early evidence of left ventricular enlargement is the elevation and elongation of the lower left cardiac contour with corresponding shortening of the left middle contour With further elongation of the outflow tract the left ventricular border is lower and more closely in contact with the diaphragmatic shadow Later when the inflow tract also becomes enlarged, the apex of the left ventricle becomes broad rounded and displaced to the left, so that the transverse diameter may also be increased (Fig 40A)

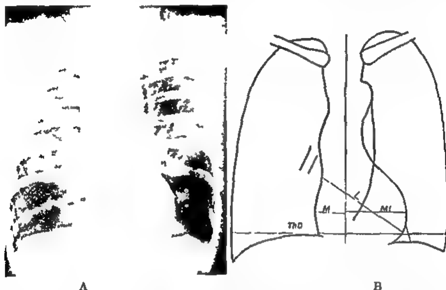

Fig 39 A Left ventricular hypertrophy in essential hypertension Increased convexity of left ventricular contour No increase in transverse or long diameters or in cardiothoracic ratio So-called concentric hypertrophy

B Sketch of *A* showing measurements Ml = 7 8 cm Mr = 3 8 cm TD = 11 6 cm ThD = 27 6 cm L = 12 6 cm

Although the transverse diameter may be increased with left ventricular enlargement there is usually a greater increase in the long diameter

Since the principal expansion of the left ventricle is dorsad enlargement of this chamber is best seen in the left anterior oblique position (Fig 40*B*) It produces a bulge in the lower posterior contour obliterating the retrocardiac space and overlapping the spine normally clear retrocardiac space is encroached on by the large left atrium or obliterated except for a small triangular area just above the diaphragm At the same time the left main bronchus may be elevated and flattened and the angle of bifurcation of the trachea increased [41, 75] In the left oblique view obliteration of the normal clear area between the upper border of the left atrium and the left main bronchus precedes elevation or obstruction of the latter

Fig 40 *A* Left ventricular enlargement in advanced aortic insufficiency Elongation and elevation of left ventricular contour with increased rounding and displacement to the left
B Same case Left oblique view Posterior bulging of left ventricular contour (arrows) Obliteration of retrocardiac space and encroachment on spine

It is important to distinguish left ventricular enlargement from displacement of the cardiac shadow to the left In normal individuals apparent enlargement of the left ventricle is usually due to a high diaphragm It should also be emphasized that displacement of the left lower cardiac contour to the left may be caused by enlargement of the right ventricle (see below) See also Fig 121 (p 662)

Left Atrium

When the left atrium enlarges, it does so chiefly posteriorly and later to the right However in the posteroanterior view the enlarged left atrium, especially its appendage may cause a straightening of the left border or a prominence of the middle salient (Fig 41*A*) To a variable degree this effect is due also to associated elevation and dilatation of the pulmonary artery The posterior enlargement is most often viewed in the right anterior oblique position (Fig 41*B*) In this view the

Enlargement of the left atrium is more clearly indicated by compression of the esophagus [■, 11, 41] In the posteroanterior view the barium outlined esophagus is abruptly and conspicuously displaced to the right and the stream is partially obstructed (Fig 42) In the right anterior oblique view the normal curve of the left atrium as outlined by the barium containing esophagus, is conspicuously deepened and displaced posteriorly (Fig 41*B*) According to Jacobson et al [35] the left lateral upright view of the chest with the esophagus opacified by barium is superior to the right anterior oblique for the demonstration of left atrial enlargement There is distinct thinning of the barium stream in the esophagus with indentation due to backward displacement of the esophagus by the large left atrium If the left ventricle is enlarged the heart is in contact with the esophagus down to the diaphragm

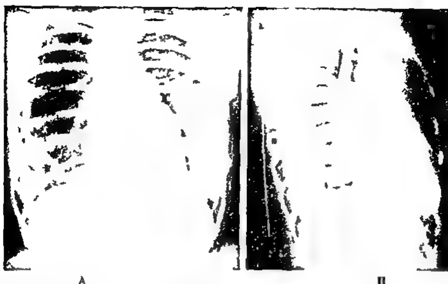

Fig 41 *A* Left atrial enlargement in mitral stenosis Prominent left middle salient due to enlarged left atrial appendage below and elevated pulmonary artery above

B Same case Right oblique view Posterior bulging of enlarged left atrium with diminution of retrocardiac space posterior displacement and compression of barium filled esophagus

Fig 42 Left atrial enlargement in advanced mitral stenosis and heart failure Compression of barium filled esophagus and displacement to the right (lower arrow) Left bronchus (upper arrow) elevated almost to horizontal position by dilated left atrium

Fig 43 Enlarged left atrium in mitral stenosis Globular shadow of hypertrophied left atrium appears as distinct density within cardiac shadow Extends on right beyond right atrial border On upper left it elevates left bronchus

If the left atrium is greatly enlarged its outline in the dorsoventral view appears on the right border (Fig 43) A double right cardiac contour may thus be formed, the upper consisting of the left atrium and the lower of the right atrium With extreme enlargement of the left atrium especially in the so called "giant left atrium," the above abnormalities are exaggerated and the entire right cardiac border is formed by that chamber, which may extend far into the right pulmonary field It may appear also on the left border as a conspicuous segment below the pulmonary artery With pronounced enlargement, the density of the left atrium also increases and its shadow can actually be distinguished within the cardiac shadow (Fig 43)

Right Ventricle

Enlargement is difficult to diagnose in its early stages on the basis of conventional roentgenograms for the enlargement is usually anterior and does not cause the chamber to reach the cardiac borders Whereas Lehman and Curry[48] reported a high degree of accuracy in the roentgen ray evaluation of right ventricular hypertrophy, Sussman and Jacobson[77] concluded that right ventricular enlargement is overdiagnosed radiologically Enlargement of the right ventricle is then recognized by its indirect effects namely elevation and rotation of the pulmonary artery which fills out the waist of the cardiac silhouette and results in straightening of the left border or convex prominence of the pulmonary salient Or the pulmonary artery may form a distinct prominence below the aortic knob (Fig 44) Furthermore the conditions responsible for right ventricular enlargement often cause pulmonary artery dilatation which also accents the left middle cardiac salient With extreme enlargement the pulmonary conus rotates clockwise on the

long axis of the heart and may participate in the left pulmonary salient Since straightening of the left border and prominence of the pulmonary salient occur most often with mitral stenosis, this distinctive configuration has been termed "mitralization" of the heart But in mitral stenosis it is the enlarged left atrial appendage and not the dilated pulmonary artery which forms the major portion of the prominent middle salient

ventricle is increased the notch between it and the left ventricle being displaced posteriorly toward the spine [56] However, doubt has been cast on this localization of the inter ventricular groove by angiocardiographic studies [■] Anteriorly, the lower cardiac border, representing the right ventricle, bulges prominently and may form a conspicuous angulation where it joins the contour of the right atrium above it

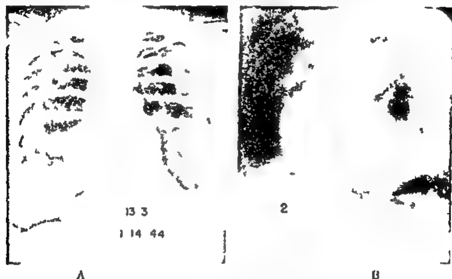

Fig 44 *A* Enlargement of right ventricle Chronic cor pulmonale Prominence and elongation of left middle (pulmonary) segment due to dilated elongated pulmonary artery Right ventricle does not reach cardiac borders in this view In right oblique view enlarged right ventricle bulged anteriorly obliterating retrosternal space
B Angiocardiogram same case Left oblique view Opacification of pulmonary artery with Diodrast shows pronounced dilatation of that vessel

Enlargement of the outflow tract of the right ventricle may be observed in the right anterior oblique as an anterior projection of the lower contour toward the sternum and in lateral views by obliteration of the retro sternal space

When the right ventricle is conspicuously enlarged (in its inflow as well as outflow tracts) it may rotate sufficiently to form most or all of the left cardiac border including the apex of the heart The original apex is elevated by the enlarged right ventricle with a resultant characteristic rounding of the lower left contour (Fig 121) The enlarged right ventricle may displace the right atrium to the right Both of these factors tend to increase significantly the transverse diameter of the heart

Enlargement of the inflow tract is best seen in the left anterior oblique position The diaphragmatic surface formed by the right

Angiocardiography discloses right ventricular hypertrophy by a change in the curvature of the interventricular septum Normally the septum is convex to the right, with right ventricular hypertrophy unaccompanied by left ventricular hypertrophy the septum becomes straightened and later convex to the left

Right Atrium

When the right atrium enlarges it expands chiefly to the right but also upward and posteriorly Roentgenoscopically, its enlargement is denoted in the posteroanterior view by outward displacement of the right lower cardiac contour Displacement to the right may, however, be caused also by enlargement of the right ventricle occasionally and by that of the left ventricle rarely When the displacement reaches the right midclavicular line, the right atrium is definitely enlarged but this is usually part of a generalized cardiac en

Fig 45 Generalized chamber enlargement Mitral aortic and tricuspid valvular disease Right atrium enlarged to right and upward Left atrium extends to both borders

largement or is due to combined mitral, aortic and tricuspid valvular disease (Fig 45) or congenital atrial septal defect

In the right anterior oblique position, the enlarged right atrium encroaches on or obliterates the lowermost portion of the retrocardiac space but it does not displace the esophagus

In the left anterior oblique position, the large right atrium causes a bulge in the upper anterior cardiac segment Enlargement of the right atrium may be simulated not only by enlargement of the ventricles but rarely also by an aneurysm of the ascending aorta reaching down toward the diaphragm by an arteriosclerotic dilated descending aorta and by para-esophageal hernia

ELECTROCARDIOGRAPHIC AND VECTORCARDIOGRAPHIC SIGNS OF CARDIAC ENLARGEMENT

The electrocardiogram may indicate or corroborate the presence of cardiac enlargement The clinical and roentgenologic findings should be considered in making a diagnosis of cardiac enlargement on the basis of the electrocardiogram The electrocardiogram does not reveal uniform, generalized enlargement of the heart but may be characteristically altered by disproportionate enlargement of one of the chambers It may suggest the presence of both left and right ventricular hypertrophy

A number of factors which have been cited above as altering the size and form of the cardiac silhouette likewise alter the form of the electrocardiogram Just as we must distinguish in roentgenograms of cardiac displacement or rotation from somewhat similar ones of cardiac enlargement so we must distinguish the electrocardiographic changes due to cardiac enlargement from those caused by the position or rotation of the heart within the chest [37]

DEVIATION OF THE ELECTRICAL AXIS

The electrical axis (or spatial vector) of the heart may be deviated from its normal direction by rotation of the heart about three axes [3]

1 The *longitudinal axis* (base to apex) One visualizes the heart as if he were facing the apex The heart rotates clockwise or counter clockwise around this axis, the direction being determined by imagining the face of a clock pinned on the apex

2 The *anteroposterior axis* Imagine viewing the anterior surface of the heart and that the face of a clock is pinned on this surface The heart rotates clockwise or counterclockwise about this axis With counterclockwise rotation the position of the heart becomes transverse with clockwise rotation it becomes vertical in the frontal plane

3 The *transverse axis* (left to right) Rotation about this axis brings the apex of the heart anteriorly or posteriorly

The Recognition of Axis Deviation

1 Mean Electrical Axis One means of discovering deviation of the electrical axis from the normal or usual is to determine the vector representing the mean electrical axis of the heart by the Einthoven triangle or triaxial reference system, and note the angle of deviation from the horizontal (see p 36) (Figs 18 19) Normally the electrical axis of the heart is directed downward and to the subject s left making an angle of 0° to 90° with the horizontal When the electrical axis is rotated counterclockwise or to the left, the angle of deviation becomes negative when the electrical axis is rotated clockwise or to the right the angle of deviation becomes more than 90° In infancy the electrical axis is greatly deviated to the right (100° to 150°) [62]

2 Vectorcardiogram Deviation of the electrical axis may also be recognized from the frontal plane projection of the vectorcardiogram Left axis deviation is disclosed by a counterclockwise loop with its long axis making an angle between 0 and minus 90° with the horizontal Right axis deviation is indicated by clockwise inscription of the QRS loop with its long axis beyond + 90° Furthermore careful observation of the spatial position of the initial and terminal vectors of the QRS loop and of the width of the loop in each portion reveals the position and type of rotation of the heart and aids in differentiating rotation of the heart from right and left ventricular hypertrophy, bundle branch block and myocardial infarction [89]

3 Ventricular Gradient (p 51) In normal subjects the direction of the ventricular gradient is within the range of 0° to 90° from the horizontal deviates not more than 20° to either side of the anatomic (longitudinal) axis of the heart (H) and deviates not more than 20° to 25° to the right nor more than 35 to the left of the vector $\hat{A}_{QRS}$ In left deviation of the electrical axis the axis of $\hat{G}$ is rotated to the left so that it tends to the transverse position Furthermore it deviates further to the left than H but less than $\hat{A}_{QRS}$ With right axis deviation $\hat{G}$ becomes vertical, both $\hat{G}$ and $\hat{A}_{QRS}$ are rotated to the right of the anatomic axis of the heart (H) but $\hat{A}_{QRS}$ is rotated more than $\hat{G}$

4 Direct Inspection of Q R and S in Standard Leads *Normally the electrical* axis has been noted to be directed downward and to the subject's left at any angle of 0° to 90° with the horizontal As the heart is rotated to the left or counterclockwise on its anteroposterior axis its mean electrical axis becomes more nearly parallel to the lead I line in the triaxial reference system and more nearly perpendicular to lead III Therefore the positive voltage in lead I, represented by R_1 becomes higher and the voltage in lead III represented by R_3 becomes lower When the rotation of the electrical axis to the left (or counterclockwise) is so great that it is directed to the subject s left and upward, the angle with the horizontal becomes negative and the maximal voltage in lead III diminishes below 0° and becomes reversed This is indicated by an inverted major deflection or a deep S_3 while R_1 remains tall Electrocardiographic curves with a tall R wave in lead I (taller than R_2) and a deep S wave in lead III are said to show *left axis deviation* (Fig 19A) A Q_1 is often present but no Q_3 T_3 may be inverted and occasionally P_3

As the electrical axis of the heart is shifted to the right or clockwise, it becomes more nearly parallel to lead III and more nearly perpendicular to lead I The maximal voltage in lead III and therefore the R wave in that lead become higher while the voltage and R wave in lead I become lower As the electrical axis comes to be directed downward and to the subject's right (instead of to the left as is normal), the angle with the horizontal ex

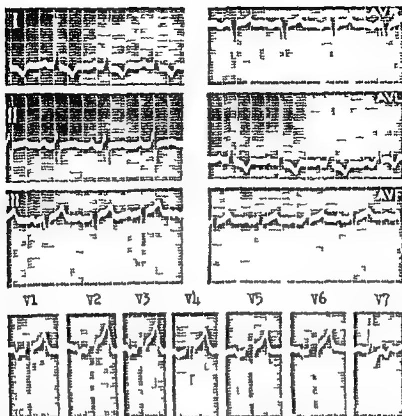

Fig 46 Enlargement of the left ventricle (left ventricular strain) Tall R_1 dominant R_1 with deep S_3 ST slightly depressed and T inverted in standard leads Small R in V_1 and deep S in right precordial leads Tall R delayed peak of R and inverted T in V_6 over left ventricle Counterclockwise rotation (horizontal heart) shown in unipolar limb leads by negative major deflection in left leg lead (aVF) and high R in left arm lead (aVL)

ceeds 90 degrees the voltage diminishes below 0 in lead I and becomes negative and the main electrocardiographic deflection is inverted Thus there is a deep S_1 while R_3 is tall (Fig 47) Electrocardiograms with a tall R_3 (taller than R_1) and a deep S_1 are described as showing *right axis deviation* There may be a Q_3 but no Q_1 T_1 and P_1 may be of low voltage or inverted

The simplest and most practical way of determining the presence of left or right axis deviation is by inspection The degree of axis deviation can be roughly evaluated by noting the height or depth of the R and S waves Thus the taller R_1 and the deeper S_3 are the greater the degree of left axis deviation and the taller R_3 and the deeper S_1 are the greater the degree of right axis deviation

5 **Unipolar Limb Leads** The features of the electrocardiogram associated with an horizontal semihorizontal vertical semivertical and intermediate position of the heart are indicated essentially by the unipolar limb leads aVL and aVF as shown in Table 1 It should be stressed that the terms vertical horizontal etc refer to position of the electrical axis and not to the anatomic position of the heart however there may be a close correlation when other modifying factors are absent

The findings in the unipolar limb and precordial leads with various cardiac positions are explained by the assumptions that the left arm electrode (and V_{5-6}) face the epicardial surface and the oncoming activation wave of the left ventricle most directly when the heart is transverse and that the left leg electrode (and V_7) face them most directly when the heart is vertical Since the dominant electromotive forces are determined by the left ventricle and a predominantly positive wave is inscribed when the activation wave approaches the recording electrode the major deflection is upward in the left arm lead (aVL) and V_{5-6} when the heart is transverse

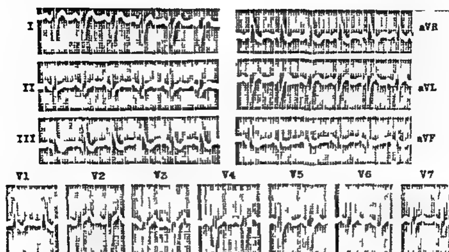

Fig 47 Enlargement of right ventricle (right ventricular strain) R_3 taller than R and deep S_1 in standard leads R tall and larger than S and T inverted in V and aVR Unipolar limb leads show upright major deflection in aVR resembling aVF with inverted major deflection in aVL indicating vertical position or clockwise rotation of the heart

and upward in the left leg electrode (aVF) *when the heart is vertical Actually there is* recorded the typical left ventricular complex Rs or qRs in the left arm lead when the heart is horizontal and in the left leg lead when the heart is vertical (Fig 47) Conversely in the horizontal heart the left leg electrode (aVF) and V_1 face the right ventricular epicardium and oncoming initial septal and right ventricular activation wave and the so-called right ventricular complex rS is recorded Or *else the predominant downward deflection is* explained as due to the electrode facing the negative side of the dominant left ventricular activation wave According to vectorcardiographic theory, the different patterns are explained not by proximity of an electrode to one or the other cardiac chambers but as the result of a change in the direction and magnitude of the spatial vector of all the electromotive forces of both ventricles when the *orientation of the heart is altered*

The Electrical Axis in Relation to Anatomic Axis of the Heart and Body Build

There is a fairly good but imperfect relationship between the electrical and the anatomic (longitudinal) axis (H) of the heart [19] The direction of the electrical axis like that of the anatomic is downward and to the left Furthermore counterclockwise rotation of the electrical axis in the frontal or horizontal plane i e deviation to the left usually accompanies a counterclockwise or leftward rotation of the heart on its longitudinal or anteroposterior axis i e a transverse position of the heart Similarly, clockwise rotation of the electrical axis (deviation to the right) usually accompanies clockwise rotation of the heart or a vertical position

Deviations in the electrical axis of the heart may be quantitatively more extensive than changes in the anatomic axis [27] It would lead to absurdity to attempt to localize the anatomic *axis in the direction and vicinity of the*

Table 1 Identifying Electrocardiographic Characteristics of Electrical Position of the Heart

	HORIZONTAL	SEMIHORIZONTAL	VERTICAL	SEMIVERTICAL	INTERMEDIATE
aVL	Tall R No S Similar to V_6	Medium R No S Similar to V_6	Small R Deep S Similar to V_1	Small R Small S	Small R No S Similar to V_6
aVF	Small R Deep S Similar to V_1	Small R Small S	Tall R No S Similar to V_6	Medium R No S Similar to V_6	Small R No S Similar to V_6

electrical axis when the deviation of the latter is extreme for example beyond plus 100° or beyond minus 30 As we shall see the electrical axis is determined by other factors besides the anatomic position of the heart in the thorax

Howard and Gertler[34] attempted to correlate the deviation of the electrical axis with body build as classified by Sheldon s method of somatotyping[11] The latter based on anthropometry and regarded as the most satisfactory index for expressing body build classifies body build into endomorphy ectomorphy and mesomorphy Left (electrical) axis deviation was correlated with endomorphy, right axis deviation with ectomorphy With increasing obesity (not muscularity) and compactness of the body there was a greater tendency to leftward deviation of the electrical axis, with more linear build to right axis deviation On the other hand the correlation of axis deviation with weight, chest width and the ratio of height to cube root of weight (the ponderal index) was only slightly significant

Axis Deviation Due to Positional Change or Cardiac Enlargement

The electrocardiographic changes associated with deviation of the electrical axis to the left or right have sometimes been described as denoting left ventricular or right ventricular preponderance i e they were presumed to indicate disproportionate hypertrophy or enlargement of the left or right ventricle[50] Indeed left and right ventricular enlargement are common causes of pronounced left or right axis deviation but the patterns of the latter are often produced in the absence of cardiac enlargement[65] and in fact right axis deviation may occasionally be encountered in a heart with left ventricular enlargement[86]

The electrocardiographic pattern of left axis deviation of moderate degree (0 to minus 20) is normally observed in the constitutionally sthenic person with a transversely situated heart in obese subjects with a high diaphragm and in pregnant women It occurs in association with ascites After a maximal expiration left axis deviation is accentuated i e R is increased in lead I diminished in lead III and the height of T increases in leads I and II and in the precordial leads[45] When the electrical axis is more markedly deviated to the left (i e when the angle alpha made with the horizontal axis is beyond minus 20°, and especially beyond minus 30°), it is usually indicative of myocardial disease

Dilatation and hypertrophy of the left ventricle and left bundle branch block are usually associated with left axis deviation, which may be marked Left ventricular enlargement may modify the electrical axis both by rotating the heart and by modifying the direction and magnitude of the electromotive forces generated by the heart Bundle branch block modifies the apparent electrical axis by altering the development of potential variations in the two ventricles

The electrocardiographic pattern of right axis deviation of moderate grade (plus 90° to 100°) is normally observed in asthenic individuals with centrally situated vertical or drop heart and in early infancy It is commonly observed in pulmonary emphysema and a low diaphragm After a deep inspiration right axis deviation may be produced or accentuated especially in the standing position R decreases in lead I, and T decreases or may become slightly negative[45] A shift of the mediastinum and heart to the left tends to produce right axis deviation A marked right axis deviation (beyond 110° to 120) usually denotes myocardial disease and is not due to positional change alone but it may be observed in the normal infant less than six months old[53] Right axis deviation is commonly associated with right ventricular dilatation and hypertrophy and with right bundle branch block and may be of marked degree

THE ELECTROCARDIOGRAM IN HYPERTROPHY OF THE LEFT VENTRICLE (LEFT VENTRICULAR STRAIN)

Certain electrocardiographic changes have been correlated empirically with left ventricular hypertrophy although one or more of the stated electrocardiographic criteria may be absent in proven cases of hypertrophy of the left ventricle[68, 154] The observed electrocardiographic changes are explained on the basis of an hypertrophied thickened free wall of the left ventricle Hence (1) greater electromotive forces are generated the R wave is taller in electrodes facing the epicardial surface of the left ventricle (V_5 and V_6) and in electrodes facing the negative aspect of the activation wave of the left ventricle (V_1 and V_2) there is a deep S wave (2) a longer period is required for the activation wave to travel from the endocardial to the epicardial surface of the

thickened left ventricle and therefore the duration of the QRS may be slightly increased, (3) for the same reason the time of arrival of the activation wave at the region underlying left precordial electrodes (V_5 and V_6) is delayed i e , the intrinsicoid deflection is delayed

When there is a marked increase in the electromotive forces associated with depolarization of the hypertrophied left ventricle there is a secondary and similar increase in the forces of repolarization Thus the leads showing very tall R waves may also disclose a depressed S T segment and inverted T waves since the greater the area of the positive depolarization complex (QRS) the greater the area of the negative repolarization complex (S T and T) In the absence of myocardial disease the ventricular gradient is unaltered in ventricular hypertrophy Hence the positive forces of the ventricular gradient may not be sufficient to overcome the increased negative forces of repolarization of the hypertrophied ventricle the T wave is therefore negative and the S T segment may be depressed The negative T wave is a secondary T wave change (p 51)

The following electrocardiographic changes are usually observed in conditions associated with isolated or predominant left ventricular hypertrophy (in hypertensive heart aortic valvular heart disease coronary heart disease with left ventricular failure, congenital subaortic stenosis or tricuspid atresia) (Fig 48*B*)

1 *Multiple unipolar precordial leads* provide the most reliable evidence of left ventricular hypertrophy [17]

(a) The R wave in V_5 and V_6 overlying the hypertrophied left ventricle is of high voltage and there is usually a Q wave of moderate depth R in V_5 exceeds 26 mm and R in V_5 plus S in V_1 exceed 35 mm [31]

(b) There is a deep S in leads V_1 and V_2 and perhaps in V_3 but the R wave is small or minute in these leads

(c) The transition point at which R becomes as high as or higher than S shifts from about V_3 to V_2 or V_1 when there is counterclockwise rotation, or to V_4 or V_5 when there is clockwise rotation

(d) The peak of the R wave, or presumed onset of the intrinsicoid deflection in leads $V_{5,6}$ occurs relatively late in the QRS interval, i e the interval from the beginning of the QRS to the peak of R is 0 05 second or more instead of the normal maximum of 0 035 second in left precordial leads The intrinsicoid deflection occurs normally in the right precordial leads V_1 and V_2 (about 0 01 to 0 02 second after the onset of the QRS)

(e) The QRS interval in left precordial leads may be slightly prolonged to 0 10 or even 0 11 instead of a normal duration of about 0 08 second

(f) The T wave in left precordial leads is blunted and low or becomes inverted The S-T segment is depressed in the same leads According to Wood and Selzer [31] left axis deviation without left ventricular hypertrophy may be associated with inversion of the T wave in V_3 and occasionally in V_4 but not in V_5 In right precordial leads (V_1, V_2) the S T segment is often slightly elevated and the T wave upright and tall in left ventricular hypertrophy

2 The electrocardiographic changes *in the unipolar limb leads* vary somewhat according to the position of the heart

(a) There is increased voltage of the R wave (more than 11 mm) widening of the QRS to 0 10–0 11 mm and delayed intrinsicoid deflection in the lead facing the left ventricle, usually aVL

(b) The S T segment is depressed and the T wave inverted in the lead with the tall R usually aVL

(c) When the position of the heart is vertical and the electrical axis is deviated to the right the left ventricle faces the left leg (aVF) and a tall R, depressed S T and inverted T wave are observed in aVF

3 *In the standard limb leads,*

(a) There is usually *left axis deviation* S_3 is of greater amplitude than R_3 R_1 is taller than R_2 or R_3 This is particularly suggestive of left ventricular hypertrophy if left axis deviation is pronounced (the axis is located between minus 20° and minus 60°)

(b) *R_1 or S_3 or both may have an abnormally high voltage* (above 1 7 mv) Or the sum of R_1 and S_3 exceeds 2 4 mv (24 mm)

(c) *S T_1 is depressed and S-T_3 may be slightly elevated T_1 is very low or inverted and T_2 may also be low or inverted* In cases of left axis deviation due to rotation with transverse position of the heart but without hypertrophy, there may be inversion of the T wave in lead III but not in lead I [28]

(d) When the heart has a vertical position there may be a normal electrical axis or right

axis deviation despite the development of left ventricular hypertrophy [1, 74] The presence of left ventricular hypertrophy is then indicated in the precordial leads, while the position of the heart is disclosed by the unipolar limb leads When left ventricular hypertrophy is associated with a normal electrical axis the T waves may be inverted in leads I II and III, or when it is associated with right axis deviation (S_1 prominent and R_3 larger than R_1) the T waves are inverted in leads II and III Whereas Q waves are often present in lead I when there is left axis deviation with hypertrophy, Q waves are present in leads II and III when the electrical axis is normally situated or deviated to the right

Left ventricular hypertrophy is distinguished from left axis deviation without hypertrophy by the high voltage of the R, delayed onset in R peak, S T depression and inversion of T wave in left precordial leads Its electrocardiographic differentiation from left bundle branch block (p 398) may be difficult Essentially it depends on the greater prolongation of the QRS and later onset of intrinsicoid deflection with bundle branch block Sometimes left ventricular hypertrophy is associated with an electrocardiogram simulating that of myocardial infarction and conversely myocardial infarction may be associated with the electrocardiographic pattern of left ventricular hypertrophy (p 527)

THE VECTORCARDIOGRAM IN LEFT VENTRICULAR HYPERTROPHY

The following vectorcardiographic changes are observed in left ventricular hypertrophy by the cube method of Grishman[12]

The *direction* of inscription of the QRS loop is normal namely counterclockwise in the horizontal projection, clockwise in the sagittal and usually counterclockwise in the frontal But in vertical hearts the direction of inscription may be clockwise in the frontal plane projection

The QRS vector loops are oriented more posteriorly and more to the left than in normal hearts (Fig 48)

The long axis of the QRS loop lies usually between minus 30 and minus 50 in the horizontal plane projection and between plus 5° and plus 40 in the frontal plane

The QRS loop may not be closed prior to inscription of the T loop (corresponding to ST segment deviation) The *orientation of the T loop* is altered the loop lying in a segment opposite the QRS loop, and the axis of the T loop forming approximately a 180° angle with the axis of the QRS loop This corresponds in the electrocardiogram with T waves directed opposite to the major deflection of the QRS Occasionally the QRS fails to close prior to inscription of the T loop corresponding to the RST depression in the electrocardiogram

THE ELECTROCARDIOGRAM IN RIGHT VENTRICULAR HYPERTROPHY

Genesis of Electrocardiographic Pattern

Two possible factors appear to be concerned in the genesis of the electrocardiographic pattern associated with right ventricular hypertrophy (1) hypertrophy of the muscle fibers and consequent thickening of the right ventricular wall, and (2) clockwise rotation of the heart as the right ventricle enlarges anteriorly and to the left

Clockwise Rotation Theory According to one theory which is based chiefly on studies with intracardiac leads and direct leads at operation the electrocardiographic pattern in right ventricular hypertrophy is determined by extreme clockwise rotation of the heart so that the posterobasal portion of the left ventricle faces the right precordial leads V_{3R}, V_E and V_1 [44, 88] while the right ventricular epicardium faces the electrodes situated at V_2 or V_3 to V_4 Thus tall R waves in V_1 V_E and V_{3R} are produced by electromotive forces generated by the rotated left ventricle and not by the thickened right ventricle The rS pattern in precordial leads further to the left (V_2 to V_6) is attributed to rotation of the hypertrophied right ventricle, which has come to lie beneath the left precordial electrodes The r of the rS is the representation of initial septal and right ventricular activation whereas the S preresents the left ventricular activation wave which is now traveling *away* from the left precordial electrodes

In the normal heart and in left ventricular hypertrophy, Q waves are often present in left precordial leads but not in those on the right (V_1), because of initial septal activation from left to right In right ventricular hypertrophy, Q waves are frequent in *right precordial leads* not left This also accords with the rotation theory since the septal activation wave from left to right would now be directed

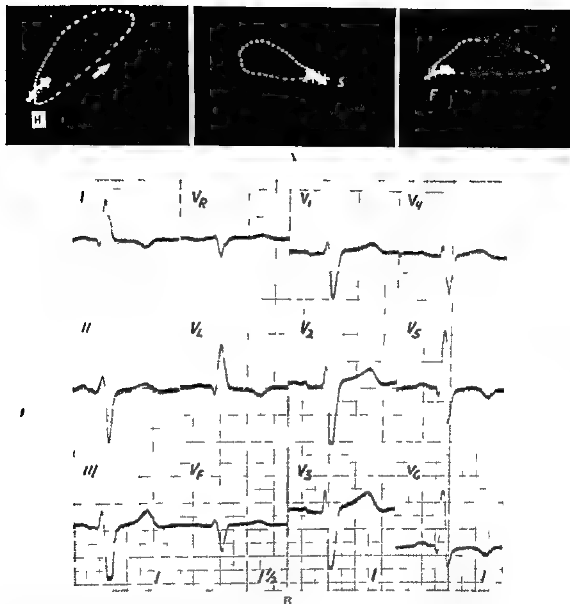

Fig 48 4 Vectorcardiogram indicating left ventricular hypertrophy in a 62 year old subject H horizontal S sagittal F frontal plane projections Counterclockwise in horizontal plane Vectorcardiographic loop is directed posteriorly to the left and superiorly
B Electrocardiogram in same case at 50 mm per second

toward left precordial leads over the right ventricle where a positive wave is inscribed, and away from right precordial leads over lying the left ventricle, where a negative (Q) wave is inscribed [21]

Other findings in right ventricular hypertrophy are also in harmony with the theory of rotation, according to which a left ventricular activation pattern (Rs or qR) is observed in right precordial leads (e g V_1) and a right ventricular pattern (rS) in left precordial leads (e g, V_5 V_6) Thus there is no widening of the QRS complex in right precordial leads because the underlying left ventricle is not hypertrophied The delay in onset of the intrinsicoid deflection in right precordial leads to about 0 04 second instead of 0 02 second is interpreted not as a delay in right ventricular intrinsicoid deflection but as the normal onset of the intrinsicoid deflection in the underlying left ventricle

One important objection to this hypothesis is the observation that the T wave is often inverted (and the S T segment depressed) in

right precordial leads, which, according to the rotation theory, reflect left ventricular activity But since the left ventricle is usually normal there is no reason for these ST and T wave changes

Increased Right Ventricular Potentials The other theory regarding the genesis of the electrocardiogram in right ventricular hypertrophy attributes the changes chiefly to the hypertrophy of the right ventricle per se in consequence of which greater electromotive forces are generated, sufficient to dominate those of the left ventricle Therefore, tall R waves larger than S are recorded in right precordial leads over the right ventricle The delay in onset of R peak is explained by the longer time it takes for the activation wave to travel from endocardium to epicardium of the thickened right ventricular wall ST T wave negativity is secondary to an increase in the voltage and sometimes to the duration of depolarization of the hypertrophied right ventricle Other changes are due to clockwise rotation of the heart but the latter is not primarily responsible for the findings in right precordial leads The electrocardiographic changes of right ventricular hypertrophy have also been well correlated with increased pulmonary resistance increased pulmonary arterial and right ventricular pressures[46, [illegible], 47] but the manner in which such pressure elevations produce the electrocardiographic alterations is not clear

The chief objection to this explanation of the electrocardiographic pattern is that the right ventricle even when hypertrophied is much thinner than the left ventricle except possibly in some cases of mitral stenosis with left ventricular atrophy and some cases of congenital heart disease It is therefore difficult to explain either dominance of right ventricular over left ventricular forces or more particularly the greater delay in onset of intrinsicoid deflection in right precordial leads (V_1) than in left (V_6) if the former represents the activation wave through the thinner, though hypertrophied right ventricle

Vectorcardiographic Theory By this theory in contrast to the theory that recorded potentials are dependent on proximity of the precordial electrode to the right or left ventricle the electrocardiographic pattern of right ventricular hypertrophy is not determined by the thickness of the hypertrophied chamber wall or by the exact relation of a given electrode to the right or left ventricle Rather it is determined by the effect of hypertrophy and rotation on the summation of spatial vectors of combined ventricular activity from moment to moment

The Electrocardiographic Pattern of Right Ventricular Hypertrophy

In many cases of right ventricular hypertrophy especially in most cases secondary to chronic pulmonary disease the degree of hypertrophy is slight and its effect on the electrocardiogram insignificant [illegible] This is presumed to be due to the preponderant effect of left ventricular forces even when the right ventricle is somewhat hypertrophied The electrocardiogram may appear normal or show only a vertical position On the other hand when the electrocardiogram does show a pattern of right ventricular hypertrophy, the latter will usually be confirmed at autopsy [illegible] The electrocardiogram may be of particular value in confirming the diagnosis of right ventricular hypertrophy in congenital heart disease, in which the most extreme grades of hypertrophy are found especially in interatrial septal defect pulmonary stenosis tetralogy of Fallot and pulmonary arteriolar disease [illegible]

The following electrocardiographic changes may be associated with right ventricular hypertrophy (Figs 47 and 49*B*)

1 **The Precordial Leads** (a) There is a tall R (more than 0 7 mv or 7 mm) in right precordial leads (V_1 and/or V_{3R} or V_E) Peak of R is delayed to more than 0 03 after onset of the initial complex Q is often present giving a qR complex S is absent ST may be depressed and T inverted in these right precordial leads

(b) In left precordial leads (V_5 and V_6) there is a small r and a deep S (rS pattern) R peak occurs earlier than in V_1

(c) Another pattern is characterized by a tall R with delayed peak and a small s in right precordial leads resulting in an R/S ratio of greater than 1 [illegible] The R/S ratio falls progressively from right to left precordial leads and there is a deep S in V_5 and V_6

(d) With severe right ventricular hypertrophy especially in congenital heart disease, there may be an rsR′ pattern in right precordial leads, with high voltage and delayed

peak of the R′, left precordial leads show a wide S The appearance is that of an incomplete bundle branch block [7a, 7b]

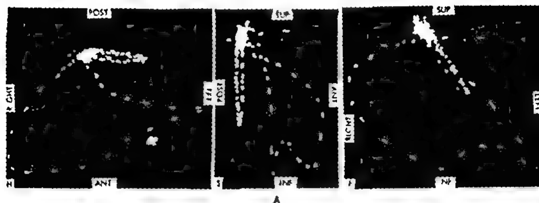
2 Unipolar Limb Leads (a) aVR shows a qR or a QR pattern with the height of R more than 5 mm (0 5 mv) and R/Q ratio greater than 1 T is inverted Occasionally there is an rSR′ pattern

(b) The other unipolar leads show varying patterns depending on positional changes Usually there is a qR pattern and inverted T in aVF and an RS pattern in aVL with upright T

3 Standard Limb Leads (a) *Right axis deviation* S_1 is of greater amplitude than R_1 R_3 is taller than R_1 or R_2 This is suggestive of right ventricular hypertrophy if the axis deviation is pronounced (mean electrical axis beyond plus 110° to 120° and S_2 deep)

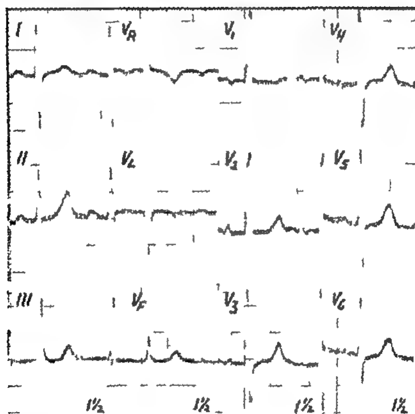
(b) R_3 and S_1 may have abnormally high voltage This finding increases the probability that right axis deviation is due to right ventricular hypertrophy

(c) T_2 and T_3 are inverted and ST_2 and ST_3 are depressed The combination of these ST T changes with right axis deviation forms the pattern of so called "right ventricular strain," often regarded as diagnostic of right ventricular hypertrophy [3] But there are exceptions [17, 24]



4 Tall or widened P waves in association merely with a vertical electrical position of the heart or in combination with the above more distinctive changes, are often observed in right ventricular hypertrophy

Donzelot et al [14] correlated a variety of electrocardiographic patterns with specific congenital cardiac lesions Tetralogy of Fallot was usually associated with an 'adaptation' pattern characterized by an inverted QRS and a slightly elevated ST segment in lead I, upright T waves in II and III tall R in V_1 and V_{3R} and aVR, and upright T waves in V_5 and V_6 Interatrial septal defect was usually associated with the 'surcharge' pattern characterized by incomplete bundle branch block (rR′ in V_1 and V_{3R}) Pulmonary stenosis was usually associated with the "barrage" pattern characterized by ST depressions and T wave inversions in leads II, III, V_1 V_5 and aVF and by an inverted QRS slightly elevated ST and upright T in leads I and aVL Cabrera and Monroy,[7] and Sodi Pallares and Marsico [72] described similar patterns, which they related to systolic or diastolic overloading Systolic overloading of the right ventricle, e g, in pulmonic stenosis was associated with tall R waves and inverted T waves in right precordial leads Diastolic overloading, e g, in interatrial septal defect, was associated with incomplete or complete right bundle branch block



The electrocardiographic pattern of right ventricular hypertrophy must be distinguished from that of right axis deviation due to positional change without hypertrophy from that of right bundle branch block and from that of certain instances of myocardial infarction Delay in onset of the intrinsicoid deflection (peak of R wave) in right precordial leads R taller than 7 mm in V_1 or taller than 5 mm in lead aVr and mean electrical axis beyond plus 110° to plus 120° all indicate right ventricular hypertrophy rather than mere rotation without hypertrophy Right bundle branch block is discussed on page 399 The QRS complex in V_1 is of normal duration in right ventricular hypertrophy prolonged to 0 11 or 0 12 in incomplete block or to 0 13 second or more in complete right bundle branch block But there are exceptions to this rule of differentiation Occasionally incomplete bundle branch block is associated with right ventricular hypertrophy notably in congenital cardiac lesions the presence of hypertrophy as well as branch block is suggested by the tall R waves in V_1 and aVr The differentiation from acute myocardial infarction is discussed on page 521

THE VECTORCARDIOGRAM IN RIGHT VENTRICULAR HYPERTROPHY

The vectorcardiographic patterns differ with the reference system employed Lasser et al [44] using Grishman's cube method of electrode placement observed three distinct five vectorcardiographic patterns, depending on the degree of right ventricular hypertrophy, in cases of congenital heart disease in which an rsR′ pattern occurred in right precordial leads of the electrocardiogram The QRS vector loops were oriented mostly to the right and anteriorly (Fig 49) With increased degree of hypertrophy the loops tended to deviate superiorly and posteriorly This orientation accounts for the occurrence of tall R waves in right precordial leads and in aVr Sometimes the initial component of the QRS loop is inscribed posteriorly and to the left [20] The direction of inscription of the QRS

A

B

Fig 43 *A* Vectorcardiogram indicating right ventricular hypertrophy in a 4 year old girl with tetralogy of Fallot The QRS loop in the horizontal projection is inscribed clockwise The vectorcardiogram is directed inferiorly anteriorly and to the right

B Electrocardiogram in the same case at 50 mm per second

loop is often altered notably a clockwise inscription in the horizontal plane projection instead of the normal counterclockwise[23] The T and QRS loops are divergent accounting for inverted T waves in leads with a predominant upright QRS complex Flek et al[15] observed similar vectorcardiographic changes in mitral stenosis as well as in congenital heart disease Richman and Wolff[6] also described in detail characteristic and diagnostic vectorcardiographic patterns in right ventricular hypertrophy

Certain advantages have been claimed for vectorcardiography over electrocardiography

in the diagnosis of right ventricular hypertrophy.[13] The vectorcardiogram may demonstrate that there is no right ventricular hypertrophy when electrocardiograms suggest its presence, especially in normal subjects with a thin chest wall. Or the vectorcardiogram may indicate right ventricular hypertrophy when this is not diagnosed from the electrocardiogram. It is uncertain whether the latter possible deficiency is due to inadequate leads or a failure in proper analysis of the electrocardiogram.

The vectorcardiogram is said to enable differentiation of right ventricular hypertrophy from right axis deviation without hypertrophy, from incomplete bundle branch block and from myocardial infarction, when such differentiation may be difficult or impossible by electrocardiography. The right axis deviation observed normally in infants and young children usually may be distinguished from that due to right ventricular hypertrophy by the normal direction of inscription and normal general configuration of the QRS loop in the former.[47] Lasser et al.[48] differentiated right ventricular hypertrophy from incomplete bundle branch block in cases with an rSR′ electrocardiogram in right precordial leads. In right ventricular hypertrophy the orientation and inscription of the QRS loop are abnormal, but the terminal segment is inscribed with normal velocity. In bundle branch block the initial segment of the QRS loop is inscribed *normally, but there is* an additional terminal appendage directed anteriorly and to the right, with its angular velocity reduced so that the time markings are close together (p. 401).

THE ELECTROCARDIOGRAM IN COMBINED VENTRICULAR HYPERTROPHY

Hypertrophy of both ventricles may occur, notably in combined mitral stenosis and aortic valvular lesions and with the coexistence of diseases causing left and right ventricular hypertrophy, e.g., hypertension and cor pulmonale. Usually there is predominant hypertrophy of either the right or left ventricle and the electrocardiographic pattern is determined by that predominance but often the presence of both obscures the electrocardiographic pattern of either.[51] Pagnoni and Goodwin[53] studied the unipolar lead electrocardiograms in 51 cases of combined ventricular hypertrophy confirmed at autopsy. In 13 there were electrocardiographic signs of left ventricular hypertrophy only, in 10 of right ventricular hypertrophy, in 4 of left bundle branch block, in 2 of right bundle branch block, in 8 non specific changes, and in 13 changes regarded as indicative of combined ventricular hypertrophy. The most suggestive feature was the association of changes denoting a vertical heart (p. 110) with concomitant evidence of left ventricular hypertrophy, e.g., delay in peak of R wave in V_5 to more than 0.05 second, and ST segment depression and T wave inversion in V_5. Another combination suggesting combined ventricular hypertrophy included the above evidence of left ventricular hypertrophy, together with S greater than r in V_5 or R greater than q in aVr and an enlarged P in V_1, or inverted T in V_1 in adults, signs usually associated with right ventricular hypertrophy.

THE VECTORCARDIOGRAM IN COMBINED VENTRICULAR HYPERTROPHY

Whipple and Levine[44] described a vectorcardiographic pattern which appeared to be closely related to combined ventricular hypertrophy as seen in 8 patients whose hearts were examined at autopsy. The characteristic feature was a very narrow loop (length at least six times that of depth) in the horizontal plane (cube method). The loop was directed to the left and not more than 20° posteriorly. The electrocardiograms had shown probable *combined ventricular hypertrophy in 3 of the* 8 cases, left ventricular hypertrophy in a vertical heart in 2, left ventricular hypertrophy in 1, possible left ventricular hypertrophy in 1, and right ventricular hypertrophy with a delayed intrinsicoid deflection over the left precordium in 1.

THE ELECTROCARDIOGRAM IN ENLARGEMENT OF THE ATRIA

Enlargement of the atria may produce electrocardiographic changes because of hypertrophy of the wall, dilatation of the chambers, rotation of the electrical axis in the course of enlargement, or disease of the atrial wall. The electrocardiographic changes observed include notching of the P waves, and increase in their amplitude or in their duration. According to rigid criteria, the amplitude of the P wave is abnormally increased if its height, measured in one direction from the isoelectric level, exceeds 3 mm. (0.3mv.) in any

standard bipolar extremity lead, or 2 5 mm in any precordial or augmented unipolar extremity lead As a rule, however, P is abnormally tall if it exceeds 2 5 mm in lead II 2 mm in lead I, 2 mm in any precordial lead or 1 5 mm in any augmented unipolar extremity lead P is wide if it exceeds 0 10 second in any extremity lead An abnormally high amplitude has been attributed to hypertrophy with consequent increase in the generated electromotive forces and widening of waves in leads II and III and aVF Right atrial enlargement has been associated with large biphasic waves with a prominent intrinsicoid deflection in right precordial leads V_1 or V_2 and V_3 [75, 17] On the other hand there is evidence that no intrinsicoid deflection of the right atrium can be obtained by available electrode placements because of the distance of the electrode from the surface of the right atrium Therefore it is believed that precordial leads with large biphasic P waves

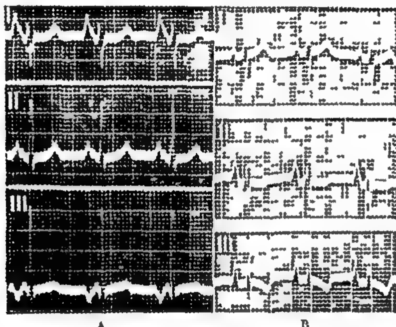


Fig 50 4 (Left) atrial enlargement in mitral stenosis P waves tall notched and widened in leads I and II Right ventricular strain
B (Right) atrial enlargement in chronic cor pulmonale secondary to asthma and obstructive emphysema P waves tall and pointed (peaked) in leads II and III but not widened Right ventricular strain or right axis deviation

the P to dilatation of the atria with consequent prolongation of the depolarizing process or to disease within the wall Notching has been related either to irregularly distributed areas of disease to unequal dilatation of the left and right atria (usually predominantly or exclusively the left) or most probably to a delayed intrinsicoid deflection in left atrial leads

Atrial activity may be best disclosed by esophageal leads or right parasternal leads [78, 8] Left atrial enlargement is most likely to be associated with widening and notching of the P waves usually in leads I and II and in aVL and aVR whereas right atrial enlargement is usually characterized by tall, narrow, peaked in V_1 represent late activation of the *left* atrium and indicate hypertrophy of that chamber [80]

Broad notched and frequently tall P waves usually in leads I and II have been described as mitral P waves and have been associated with mitral stenosis[85, 79] (Figs 50*A*, 51*B*) According to Berliner and Master [4] notching of the P wave occurs in uncomplicated mitral stenosis but broad P waves of very high amplitude are usually found when tricuspid disease is also associated Enlargement of the right atrium secondary to chronic pulmonary disease has been characterized by tall sharply peaked P waves in leads II and III and in aVF (pulmonary P waves) (Figs 50*B*,

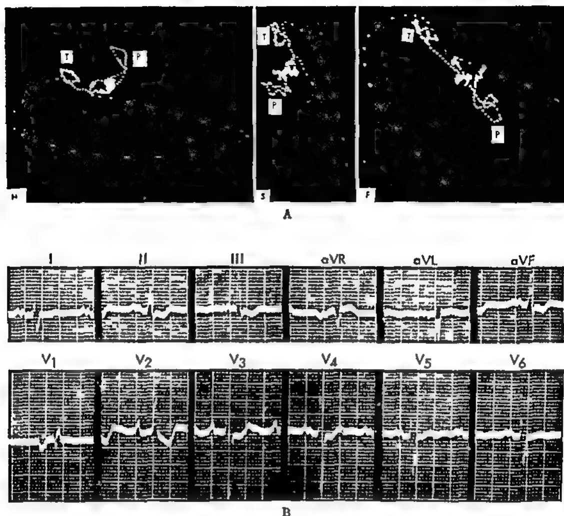

Fig 51 *A* Vectorcardiogram indicating left atrial enlargement The P loop is directed mainly posteriorly and somewhat to the left inferiorly
B Electrocardiogram in same case

52*B*) [40, 68, 71] This type of pulmonary P wave may be observed in normal hearts owing to a vertical position of the heart with forward displacement of the apex perhaps related to an associated low diaphragm and pulmonary emphysema [11] The tall pulmonary P waves may be observed transiently as when they appear during an attack of bronchial asthma and disappear after the attack subsides [9] Observations such as these as well as the lack of correlation of pulmonary P" waves with right atrial hypertrophy [9] tend to support the assumption that "pulmonary P waves are the result of cardiac rotation possibly causing atrial electromotive forces to be directed backward and toward the left leg

In congenital heart disease there is frequently an elevated P wave, maximal in lead II, without widening especially in conditions associated with right atrial enlargement as interatrial septal defect pulmonary stenosis, tetralogy of Fallot and tricuspid stenosis or atresia

In a recent study of the P wave in CR precordial leads, Thomas and Dejong[79] classified the major normal P wave patterns and described distinctive P wave changes in right and left atrial hypertrophy Right atrial hypertrophy was characterized by a tall (more than 2 5 mm) diphasic pointed or bifid P wave in right precordial leads When bifid or notched the first peak (representing right atrial activity) was taller Left atrial hypertrophy was characterized by a tall (more than 3 mm) bifid P wave with the second peak most prominent, in left precordial leads,

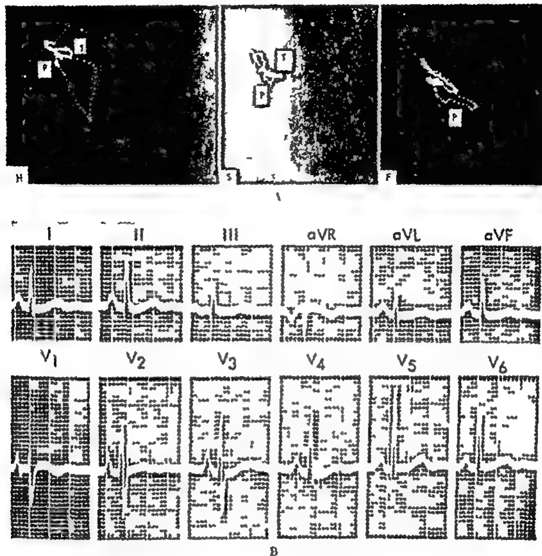

Fig 62 *A* Vectorcardiogram indicating right atrial enlargement in a case of pure tricuspid stenosis The P loop is directed mainly anteriorly and somewhat inferiorly and to the left
B Electrocardiogram in the same case (Courtesy of Dr A Grishman)

or by an abnormally long interval between peaks of a bifid P in any lead regardless of voltage Asynchronism of the two atria has been demonstrated by direct right and left atrial leads during operation [41] The left atrium contracts later than the right and accounts for the latter portion of the P wave When a bifid P occurs normally the first peak is essentially due to right and the second to left atrial activation The normal time difference between right and left atrial activity is 0 03 to 0 04 second and this is the normal interval between the peaks of a normal bifid P wave In cases of left atrial hypertrophy bifid P waves occur more frequently than in normal persons the second peak (left atrial activity) is delayed to more than 0 04 second and usually the interval between the peaks measures 0 06 second In pulmonary heart disease especially when there was distinct evidence of pulmonary hypertension there were changes indicative of right atrial hypertrophy but no increase in the intervals between peaks when bifid P waves were present In mitral stenosis evidence of left atrial hypertrophy was indicated by P wave changes with increasing frequency in relation to the severity of symptoms In one third of the cases there was evidence of right as well as left atrial hypertrophy particularly when there was evidence

of associated pulmonary hypertension In constrictive pericarditis there were P wave changes indicative of left atrial hypertrophy and occasionally of hypertrophy of both atria [9, 79] Tall pointed P waves were observed in the precordial leads in cases of isolated pulmonic stenosis or when this lesion was part of the tetralogy of Fallot or combined with other lesions [III, 79] In atrial septal defect the P changes were more suggestive of left atrial hypertrophy

VECTORCARDIOGRAM OF ATRIAL ENLARGEMENT

Instead of the normal narrow downward vertical P vector loop the vector loop in left atrial enlargement is directed anteriorly and to the left in its initial portion (Fig 51) whereas the larger terminal portion is directed posteriorly and somewhat inferiorly and leftward The loop is broader and triangular, and may be open with counterclockwise inscription in frontal and clockwise rotation in sagittal projections [8] In *right atrial enlargement* the P loop is directed anteriorly, very slightly to the left and little, if at all, downward (Fig 52) Occasionally it has a triangular appearance The loop is usually larger than normal or in left atrial enlargement, and is generally open The maximum vector is in the first portion of the loop, which is directed anteriorly In combined atrial hypertrophy there are large early anterior and large late posterior leftward forces [65a]

Chapter 6

ETIOLOGY OF CHRONIC (CONGESTIVE) HEART FAILURE

Circulatory failure has been classified into the acute and chronic forms (Chapter 4) The acute form which includes shock syncope and sudden death, is discussed in Chapter 12 *The present chapter and the succeeding five* chapters are concerned with the chronic form of circulatory failure which is generally known as congestive heart failure

This chapter presents the factors or mechanisms which render the heart incapable of maintaining an adequate cardiac output, or of maintaining it without the aid of extra cardiac compensations The etiology of congestive heart failure will be discussed under the following headings (1) Fundamental Mechanism, (2) Precipitating Clinical Causes, (3) Underlying Causes The mechanism by which this cardiac disability leads secondarily to the clinical manifestations of congestive heart failure is discussed in subsequent chapters (8 and 9)

THE FUNDAMENTAL MECHANISM OF CARDIAC FAILURE

When cardiac failure occurs shortly after a toxic, *infectious disease such as diphtheria,* we assume that sufficient muscle tissue has been destroyed or its contractility so greatly impaired by bacterial toxins that the heart is unable to maintain the circulation It is incomprehensible, however, why cardiac failure *so often develops in a patient whose valvular,* hypertensive or arteriosclerotic heart disease has appeared entirely static and well compensated Frequently we suspect a recurrent or intercurrent infection, a progressive diminution in the coronary blood supply physical strain or some other so-called precipitating factor, but we *are at a loss to understand* exactly how this factor induced cardiac failure Investigations to determine the mechanism of cardiac failure have been conducted along three lines (1) The pathologic changes in the heart which has failed (2) The relationship of cardiac hypertrophy to cardiac failure (3) The chemical changes in the heart

THE PATHOLOGIC BASIS OF CARDIAC FAILURE

Extent of Anatomic Alterations in Heart with Failure

It has long been customary to attribute cardiac failure to anatomic changes in the heart, Yet it is a striking fact that the pathologist can rarely make a diagnosis of cardiac failure by examination of the heart alone As a rule the lesions of rheumatic, hypertensive coronary atherosclerotic, syphilitic and other forms of heart disease remain essentially the same in any one of the mentioned diseases whether or not the heart has failed Frequently there is no evidence to indicate that the old valvular or myocardial lesions have undergone any recent change which might account for the onset of failure There is often no close correlation between the extent of myocardial disease or the degree of *valvular disturbance and the occurrence of* cardiac failure Extreme mitral stenosis aortic stenosis or aortic insufficiency, or severe narrowing of the coronary arteries with myocardial fibrosis and necrosis is found at postmortem examination in persons who showed no clinical evidence of cardiac failure during life Conversely the myocardium of persons with longstanding heart failure may show too few lesions to serve as an adequate anatomic basis for the clinical picture

Sometimes, of course, as in cases of multiple coronary occlusions with extensive myocardial fibrosis and infarction or of diphtheritic myocarditis there is no question that the extent and severity of the visible anatomic changes in the heart may account for the

development of heart failure Furthermore on a statistical basis the hearts in cases of cardiac failure show more conspicuous dilatation and hypertrophy more severe degrees of valvular disturbance, greater coronary narrowing or more extensive myocardial disease than the hearts of persons with similar disease but without a clinical history of heart failure Nevertheless there are so many instances in which there is a great disparity between the extent of pathologic changes in the heart and the clinical evidence of failure that the anatomic alterations in the heart cannot be considered a satisfactory, universal explanation for the occurrence of cardiac failure

Conflicting Opinions as to the Significance of Microscopic Cardiac Lesions

The myocardial basis of cardiac failure was stressed particularly because of the microscopic investigations of Krehl[10] Romberg[12] and other members of the Leipzig school of pathology Krehl[10] studied eight hearts with valvular heart disease and found significant fresh and old macroscopic and microscopic lesions in the endocardium, pericardium, myocardium and vessels In cases of typhoid fever, scarlet fever and diphtheria, Romberg[4] observed inflammatory lesions in the myocardium which he believed accounted for the symptoms of heart failure and the occasional occurrence of sudden death In cases of idiopathic cardiac hypertrophy with symptoms of failure, Krehl[10] discovered inflammatory infiltrations, degenerative changes and extensive scarring He concluded that heart failure was the result of these myocardial changes and not of the hypertrophy as such

The concept that the pathologic changes in the heart accounted for the occurrence and onset of cardiac failure received its first major attack from the investigations of Aschoff and Tawara[2] These observers showed that while inflammatory changes were often present in the myocardium in cases of rheumatic cardiovalvular disease, in many other cases of this disease and in the majority of other cases of chronic cardiac failure significant inflammatory lesions were absent or the changes were too slight to explain the development of heart failure Certain so-called myocardial abnormalities, such as a disproportion of sarcoplasm to myofibrils, pigmentation of fibers perivascular round cells and degenerative nuclear changes were demonstrated to be either normal occurrences or artifacts Aschoff and Tawara[2] concluded that, except in diphtheria, heart failure in the majority of cases of cardiovalvular disease, nephritis atherosclerosis infectious diseases, chronic pulmonary disease syphilis tumors or trauma was due not to the extent of the anatomic myocardial lesions but to disturbances caused by increased functional demands on the heart

Individual Pathologic Cardiac Abnormalities in Heart Failure

The following pathologic abnormalities have been described as a possible anatomic substratum for cardiac failure Only brief comments are made as these changes are discussed in detail in the chapters on the individual etiologic diseases In evaluating the following changes it is important to note (a) whether they are merely evidences of myocardial disease or indicative of cardiac failure (b) whether their extent, severity or location can adequately account for the occurrence of cardiac failure and (c) whether the changes are the cause or the consequence of cardiac failure

1 **Inflammatory Lesions in the Myocardium** Rheumatic heart disease is the most important example of myocardial disease with predominant inflammatory lesions But although the rheumatic lesions are usually widespread throughout the heart (p 816), an essential feature is their localization in the interstitial tissue with relatively little involvement of the muscle parenchyma It is difficult to understand how the observed pathologic changes can be responsible for heart failure when the active muscle appears intact On the other hand since cardiac failure appears frequently when there is active rheumatic myocarditis with or without significant valvular disease it is probable that the failure is due to some as yet anatomically invisible toxic functional disturbance which accompanies the anatomic interstitial lesions and impairs myocardial function

Similarly, interstitial inflammatory lesions of the heart appear in a variety of infections or infectious diseases which are occasionally accompanied by heart failure, but the pathologic lesions rarely appear adequate to explain the failure

2 **Degenerative Parenchymal Lesions in the Myocardium** Predominant degenerative changes of the myocardial fibers are seen in a variety of toxic and infectious diseases in dis

eases of metabolism such as diabetes, in anemias and vascular disturbances Usually these changes are not associated with cardiac failure But even when cardiac failure develops the anatomic lesions rarely appear to be an adequate cause

Exceptions are seen in the instances of congestive heart failure associated with *myocardial necrobiosis* Diphtheria is the classic example of myocardial failure apparently due to extensive destruction of myocardial fibers (p 908) The interstitial inflammatory lesions seen in this disease are less important secondary changes which only appear if the disease lasts more than a week or two In typhoid fever there are occasionally acute degenerative myocardial changes similar to Zenker's degeneration in the rectus abdominis and other striated muscles but cardiac failure is rare Fiedler's or isolated myocarditis which is often complicated by heart failure reveals essentially interstitial changes but occasionally there is severe fatty degeneration, autolysis and even disappearance of large portions of the myocardial parenchyma Coronary atherosclerosis with occlusion is the most important cause of necrobiosis of heart muscle Occasionally extensive areas of heart muscle are destroyed and replaced by fibrous tissue, and in these instances there is a convincing anatomic basis for heart failure Very often however heart failure develops without good correlation with the extent of the pathologic abnormalities

Among *degenerative lesions of the myocardial parenchyma* are included cloudy swelling fatty degeneration vacuolar and hydropic degeneration, as well as necrobiosis The concept of the fatty heart (*adipositas cordis*) as a clinical pathologic entity responsible for cardiac failure, heart block or sudden death has generally been discarded except in rare cases (p 629) Anemia or ischemia of the heart muscle definitely results in fatty change which appears as a characteristic linear streaking known as tigering But when heart failure occurs in hearts showing tigering there is usually an associated severe anemia or an atherosclerotic or syphilitic coronary narrowing or occlusion which accounts for both the tigering and the failure

3 **Myocardial Fibrosis** The term chronic myocarditis was formerly applied to cases in which the heart revealed more or less extensive fibrosis of the myocardium This term should be discarded because the fibrosis is rarely due to the healing of *chronic inflammatory lesions* as the name implies As a rule the fibrosis results from ischemic necrosis of the myocardium due to (a) mechanical occlusion of a coronary artery as in atherosclerotic thrombosis, (b) severe narrowing of a coronary artery[13] or its ostium as in atherosclerosis or syphilis, or (c) relative coronary insufficiency when the blood supply does not keep pace with cardiac enlargement[13] as in malignant hypertension and calcific aortic stenosis Only occasionally is the fibrosis and replacement of myocardial tissue sufficient to account for heart failure

4 **Mechanical Defects of the Heart** The pathologic lesions thus far considered have been situated in the myocardium Often the essential or predominant lesions involve the valves or consist of congenital abnormalities of the septa or great vessels These valvular or other defects usually place a disproportionate physical strain on one or more of the chambers of the heart The importance of these defects is attested by the observations that the chamber primarily affected is the one which fails first, and that the type of heart failure i e the clinical picture is determined by the failure of the chamber in question Thus with stenosis of the aortic valve the early symptoms of failure are determined by decompensation of the left ventricle, while with pulmonary stenosis it is the right ventricle which fails

These and other observations indicate the importance of mechanical disturbances independent of myocardial disease, in the development of cardiac failure However such mechanical strain cannot account for the instances of heart failure in which there are no valvular or other mechanical defects Neither is it clear why failure occurs suddenly in hearts with old valvular defects which have not recently been altered or why failure may be absent in many cases with severe mechanical defects or present in cases where these are slight Finally it should be emphasized that the cardiovascular abnormalities which increase the mechanical strain on the heart are usually associated with some myocardial disease e g, coronary atherosclerosis with essential hypertension active rheumatic myocarditis with valvular defects and in

older age groups coronary disease with rheumatic valvular defects and syphilitic narrowing of the coronary ostia with syphilitic aortic insufficiency

In conclusion neither the character extent nor localization of the visible macroscopic or microscopic myocardial lesions accounts satisfactorily for the development of cardiac failure in more than a minority of the cases On the other hand pathologic study in most cases reveals some myocardial valvular or vascular abnormality which is the *underlying basis* of cardiac failure We have yet to bridge the gap between this myocardial disease which underlies heart failure and heart failure itself The visible anatomic abnormalities may be evidence only of some important deleterious but invisible changes in the function or structure of the contractile muscle tissue In recent years the gap between cardiac disease and cardiac failure has been related to the pathologic physiology of cardiac dilatation and hypertrophy and the fundamental but invisible alterations in the muscle itself have been sought in chemical studies of the myocardium (infra) and myocardial contraction

CAUSES OF FAILURE IN THE ENLARGED HEART

The maintenance of normal cardiac function is dependent primarily on the functional capacity of the myocardium and the load against which it works The cardiovascular diseases which eventually lead to congestive cardiac failure increase the load on the heart or depress its functional capacity or both In Chapter 4 we have seen that cardiac dilatation and hypertrophy are the chief mechanisms by which the heart compensates (i e maintains its normal function) when either the mechanical load is increased or its anatomico functional capacity reduced In Chapter 5 we have noted that cardiac enlargement (dilatation and hypertrophy) occurs so often with cardiovascular disturbances that it is the cardinal clinical sign of cardiac disease Numerous experimental clinical and pathologic observations indicate that cardiac enlargement is the response to cardiac disease and that cardiac failure is the end result of a variable period of increasing cardiac enlargement Thus it has become epigrammatic that congestive heart failure is the failure of the enlarged heart We will now consider the possible factors which cause the enlarged heart to fail

1 Compensatory Limitation of Cardiac Enlargement

In disease as in health there is a limit beyond which the heart is incapable of compensating for circulatory strain In health the load of exercise may demand the maximum functional capacity of the heart beyond which unpleasant symptoms compel the individual to desist In disease the heart may be required to work continuously at or near maximum capacity because of the abnormal load of irreversible cardiovascular disease This is accomplished by cardiac enlargement but at the expense of cardiac reserve Cardiac function of the enlarged heart may be adequate with the patient at rest but the lack of reserve prevents the increase in output which physical exertion demands Eventually progressive myocardial disease e g, due to coronary atherosclerosis impairs the efficiency of myocardial contraction or diminishes the amount of available muscular tissue Consequently cardiac compensation cannot be effected regardless of the degree of cardiac enlargement The compensatory effectiveness of cardiac dilatation may be occasionally limited by the relatively indistensible pericardium but more often by progressive impairment of the physiologic fitness of the heart muscle

In the heart lung preparation Starling[13] found that the heart died within eight to ten hours Gradually the heart dilated as its functional ability deteriorated until the indistensible pericardium was filled and further dilatation was impossible Thereafter further myocardial deterioration was evidenced by a fall in cardiac output and a rising venous pressure i e heart failure

Pathologic studies also suggest that heart failure often arises when cardiac enlargement reaches the limit of its compensatory capacity Karsner, Saphir and Todd[22] found that the thickness of myocardial fibers could increase only to a relatively fixed dimension and that with increasing hypertrophy more and more of the fibers attained that maximum thickness Postmortem observations also disclose that extremely heavy hearts are usually encountered only in subjects who had suffered from congestive heart failure While cardiac enlargement is often observed without failure *chronic* congestive failure is infre-

quently seen without pronounced cardiac enlargement These observations appear to indicate that congestive failure usually develops when progressive cardiac enlargement reaches the limit of its capacity to compensate the cardiovascular strain This compensatory limit varies greatly in different hearts depending in part on differences in the contractile power and efficiency of the available heart muscle In any case, as with skeletal muscle, there is an optimum beyond which further dilatation of the heart muscle is not accompanied by increased force of contraction

2 Mechanical Inefficiency of the Enlarged Heart

Certain observations indicate that dilatation and hypertrophy, which arise as compensatory mechanisms carry in themselves the germs of failure Starling and Visscher[59] found in the heart lung preparation and Moe and Visscher[43] in the completely isolated heart that when the heart began to weaken and dilate, its oxygen consumption increased in proportion to its degree of dilatation This observation has been confirmed on the heart as a whole by Hemingway and Fee[25] and by Peters and Visscher [illegible] and more recently on the isolated cat s heart by Lorber [39] Since the tiring dilating heart continues to perform the same or a diminished amount of useful work despite its increased oxygen consumption, its mechanical efficiency is reduced below normal [21, 17]

Studies of oxidative metabolism and cardiac efficiency by means of coronary sinus catheterization and the nitrous oxide method[6] indicated a distinct difference in oxygen consumption in enlarged hearts, depending on whether the patient studied was or was not in failure [8] In the presence of increased diastolic volume of the heart without failure the myocardial oxygen consumption (and energy liberation) per unit weight of heart muscle was elevated In the presence of heart failure with increased diastolic volume, the myocardial oxygen consumption per unit weight was normal despite large increases in initial myocardial fiber length These findings were interpreted to indicate that oxidative metabolism increases with elongation in the initial fiber only in the absence of heart failure, and that heart failure is accompanied by a defective conversion of oxidative energy into useful work

One of the suggested reasons for the mechanical inefficiency of the enlarged heart is the enhanced load against which it works during the course of ventricular ejection, whereas the normal heart works against a diminishing load even though there is a rising intraventricular pressure after opening of the aortic valve [11] The load against which the ventricle contracts is equal to the intraventricular pressure multiplied by its internal surface area In the normal sized ventricle, expelling a normal stroke volume of blood, the reduction in surface area is greater than the rise in intraventricular pressure from the diastolic to the systolic level, hence the load diminishes In the enlarged ventricle only a relatively small reduction in its radius and therefore in its surface area occurs with the same stroke output, the rise in pressure exceeds the reduction in area and the load increases Because of its larger surface area the enlarged heart compared to the normal, must use more energy against a greater load during rising systolic intraventricular pressure before ejection Thus during systole, both during the isometric phase and during ejection, the enlarged heart consumes more energy than the normal although the useful work, as indicated by stroke output, is the same

It appears from the above studies that the enlarged diseased heart liberates more and more energy in proportion to its degree of enlargement As the useful work of the enlarged compensated heart remains normal in terms of cardiac output or is diminished, less and less of the increased total liberated energy is converted into useful energy during progressive cardiac enlargement Thus in humans as in the experimental animal the larger the heart the less its mechanical efficiency Mechanical inefficiency in itself does not necessarily cause cardiac failure However, it partially neutralizes the effect of increased energy liberation by the enlarged heart and thereby limits its compensatory potential [illegible] According to another school of thought cardiac failure is not associated with a reduction in mechanical efficiency but with a decreased oxygen consumption for any given diastolic size and therefore an inability to release energy [54, 33]

In attempting to transfer these varied observations to human pathology one misses data which would indicate whether there are differences in oxidative metabolism and mechanical efficiency between the elongated myocardial fiber which is greatly hyper

trophied and that which is little hypertrophied and between the elongated fiber which is greatly diseased and that which is virtually normal Clinical pathologic evidence suggests that mechanical stretch (cardiac enlargement) beyond a certain point may perse eventually lead to cardiac fatigue and failure (as in arteriovenous fistula), but disease of the heart muscle may be the determining factor in the failure of the enlarged heart

3 Physicochemical Disadvantage of the Hypertrophied Heart

When the heart dilates as a result of cardiovascular disease its muscle fibers become elongated so that a greater surface is available for physicochemical change This is probably the mechanism by which it is enabled to perform the same amount of work as before the injury But as we have seen this is accomplished with a greater expenditure of energy and less efficiency By some process still unknown (possibly because of the greater oxygen consumption or of greater surface for chemical change) dilatation is followed by hypertrophy That is the muscle fibers become thickened as well as lengthened and the diminished efficiency of the dilated heart is partly offset by a greater amount of muscular tissue But now the thickened fibers of the hypertrophied heart offer greater difficulty to physicochemical exchange with their nutrient capillaries and tissue fluids than the thinner fibers of the normal heart

The studies of Hill [9] have shown that the *rate of diffusion of oxygen through tissues* varies inversely as the square of the distance that the oxygen must traverse Thus if the thickness of a muscle fiber is doubled it would take four times as long for oxygen saturation of the fiber as before hypertrophy occurred Harrison Ashman and Larsen[25] found that the mean fiber thickness was 16 2 micra for normal hearts 24 5 micra for the enlarged hearts of persons without congestive heart failure and 31 8 micra for the enlarged hearts which had failed These figures suggest that the fibers of the moderately hypertrophied heart are unable to obtain an optimal oxygen supply and are constantly in danger of anoxemia while the fibers of the extremely hypertrophied heart are constantly suffering from some degree of anoxemia This is particularly so in the central portions of the fibers which are furthest removed from the capillary twigs on either side

This disadvantage of the hypertrophied heart with respect to oxygenation becomes intensified in the presence of tachycardia such as accompanies physical exertion For any given cardiac output the oxygen requirement increases with an increase in cardiac rate [11] At the same time tachycardia encroaches on the diastolic period during which almost all of the oxygen diffusion occurs Persistent tachycardias *due to disturbances in impulse formation and the tachycardia associated with* fever and infection also exaggerate the impairment of oxygenation of the hypertrophied heart and may precipitate cardiac failure The disadvantage of the hypertrophied heart with respect to the diffusion of oxygen probably applies also to the diffusion of other substances necessary for its nutrition and its performance of work as well as to the elimination of waste products

4 Deficient Blood Supply of the Enlarged Heart

The deficiency in oxygen diffusion through the hypertrophied muscle fibers is not compensated by a corresponding increase in the number of coronary vessels By the use of Krogh s equation for the tension differences necessary to cause oxygen diffusion between two points Harrison[24] has estimated that the normal coronary flow is just about adequate to supply oxygen to the average-sized fiber of the moderately hypertrophied heart of a person at rest But the average-sized fiber (about 40 micra) of the extremely hypertrophied heart would require a *coronary blood flow two to* three times as great as normal to receive proper oxygenation

A similar conclusion may be arrived at mathematically by considering each muscle fiber as a cylinder whose surface exposed to tissue diffusion is represented by $2\pi RL$ but whose volume of muscle mass is represented by πR^2L where R is the radius of its cross section and L its length Using 16 micra as the diameter of the average normal muscle fiber its exposed surface is $16\pi L$ and its volume $64\pi L$ In the greatly hypertrophied heart the fiber diameter may average 32 micra its surface being $32\pi L$ and its volume $256\pi L$ Thus while its active physicochemical surface through which nourishment may enter has been doubled the mass of tissue to be nourished has been quadrupled

Anatomic studies fail to reveal an increase in coronary vessels which would be necessary

to compensate for the increased requirements of the hypertrophied heart Wearn[63] found an average of one capillary per muscle fiber in the normal heart During hypertrophy the muscle fibers enlarge but the capillaries do not multiply consequently the average number of capillaries per unit area in the hypertrophied heart is considerably lower than that in the normal heart[51] Experimentally also the Shipleys with Wearn[66] found that the capillary coronary supply did not increase with the development of cardiac hypertrophy in rabbits Gross and Spark[73] noted that there was roughly an inverse relationship between the size of the heart and the number of arterioles and small arteries per unit area In hearts weighing 200 to 300 gm there was an average of 3 14 arterioles whereas in hearts weighing 500 to 900 gm there was an average of 1 13 arterioles per low power field

Despite these anatomic findings, recent studies of the coronary blood flow with the aid of coronary sinus catheterization indicate not only that the coronary blood flow per 100 gm of left ventricular muscle is normal in the enlarged heart, but also that (in one case studied) the failing like the normal, heart responds to exercise with a rise in coronary flow However efficiency declined as the heart was unable to utilize fully the energy derived from either oxygen or glucose catabolism[38]

Summary Causes for Failure of the Enlarged Heart

Cardiac dilatation and hypertrophy start as compensatory processes which by their presence reveal the existence of cardiac disease Increasing cardiac dilatation and hypertrophy mark the roadway from cardiac disease to cardiac failure Cardiac enlargement (dilatation and hypertrophy) predisposes to cardiac failure because

(1) It encroaches on cardiac reserve which is limited by the ability of the muscle fibers to elongate and to become thicker When the limit is reached, the heart can no longer compensate for additional mechanical strain or myocardial damage

(2) The enlarged heart is less efficient mechanically than the normal heart because it consumes a greater quantity of oxygen although it performs the same or a lesser amount of useful work

(3) The thickened fibers do not permit as rapid a diffusion of oxygen, nutriments and metabolites as the normal fibers In extremely hypertrophied fibers there is constant anoxemia even when a person is at rest In moderately hypertrophied fibers anoxia occurs readily during exertion or with any arrhythmia or disease which increases the heart rate and reduces the diastolic period of recovery

(4) The blood supply to the fibers of the hypertrophied heart may not increase pari passu with its enlargement Thus despite the greater requirement of oxygen because of the greater muscle mass to be nourished and the greater amount of total work, oxygen diffusion is impaired Thus there is a relative coronary insufficiency even when the coronary vessels are normal This deficiency becomes greatly intensified in the course of years if the coronary vessels become narrowed by atherosclerosis

THE CHEMICAL BASIS OF CARDIAC FAILURE

Ultimately the cause of cardiac failure must be sought in disturbances of the chemical processes which provide the energy for transformation into mechanical work Our still primitive knowledge of the chemical basis of heart failure comes chiefly from three types of investigation (1) Formerly, most studies were concerned with determinations of the chemical composition of the blood during life or of heart muscle obtained at autopsy from subjects with heart failure and from subjects with normal hearts Or studies were made of the chemical composition of blood or heart muscle in experimental animals after anoxemia or coronary occlusion since these were regarded as major factors in the production of heart failure (2) More recently the development of the technique of catheterization of the coronary sinus in conjunction with the use of the nitrous oxide method for determining blood flow has yielded important information as to oxygen consumption and the utilization of various foodstuffs in health and disease, including heart failure[8] (3) Increasing knowledge regarding muscular contraction and techniques for the in vitro study of actinomyosin, the muscle protein complex which is the basic contractile material gives promise of important progress in the direct approach to the understanding of the myocardial disturbances responsible for heart failure

Myocardial Metabolism and Cardiac Contraction[67 43 60 61 44 7]

Our knowledge of the mechanism of myocardial contraction is based chiefly on our

knowledge of contraction of skeletal muscle and the assumption that they are essentially similar Nevertheless it should be mentioned that cardiac muscle differs from skeletal muscle in several anatomic chemical and physiologic aspects, and most important in its capacity for continuous rhythmic contraction for many decades Cardiac work is largely dependent on aerobic metabolism in contrast with the activity of skeletal muscle in which metabolism is dominated by an aerobic, glycolytic systems This dependence of the heart on oxygen and its intense oxygen utilization is indicated by the very low oxygen content of its coronary sinus (venous) blood which averages 5 to 7 volumes per cent in contrast with about 14 volumes per cent for mixed venous blood Heart muscle is well adapted for its oxygen needs by its unusually rich blood supply each fiber being adjacent to one or more capillaries and its blood flow which forms 5 per cent of total blood flow by the absence of a membrane separating myofibril from capillary such as exists in skeletal muscle and by its much greater supply of oxidative enzymes (cytochromes and succinic dehydrogenase) At the same time heart muscle is more susceptible than skeletal muscle to oxygen lack because of the greater dependence of its metabolism on oxygen

Cardiac contraction involves an adequate supply of the raw materials (substrates oxygen enzymes hormones) and a sequence of complicated processes from the initiation of the activation stimulus and its transmission, to depolarization of the myocardial cell and the various chemical processes concerned with the generation and utilization of energy and their translation into contraction and relaxation of the muscle fibers It is probable that cardiac failure may result from disturbances in individual factors or in several steps in the process Investigations are designed, among other purposes to determine whether specific clinical types of heart failure can be correlated with disturbances in different stages of the contraction process and whether therapeutic measures can be utilized in more direct application to the deficiency in the contractile process which is responsible for the heart failure

The essential elements in cardiac metabolism and cardiac contraction are (1) the food stuffs or fuel which act as oxidizable substrates and serve as the ultimate source of energy, (2) actin, myosin and their conjugate actomyosin which is the contractile protein of muscle, (3) adenosine triphosphate which provides high-energy phosphate bonds ($\sim P$) to energize contraction of actomyosin (4) potassium and other ions (5) phosphocreatine (6) various enzymes, hormones and muscle proteins

Production of Energy for Contraction The *major fuel or source of energy is glycogen* which is derived from blood glucose Blood lactate and pyruvate may also be used directly, the extraction of glucose, lactate and pyruvate by the heart being proportional to the concentration of these substances in the coronary artery blood With strenuous exercise, lactate and pyruvate utilization may account for the major oxygen consumption while in starvation and acidosis the ketone bodies are used for oxidation while carbohydrate is spared Fatty acids and amino acids may also serve for energy production

After phosphorylation and intermediate steps in metabolism, glucose is broken down to pyruvate molecules, while at the same time lactate is oxidized to pyruvate with the aid of a coenzyme derived from nicotinic acid In the course of normal aerobic catabolism pyruvate molecules are eventually oxidized to carbon dioxide and water with the release of most of the energy required for cardiac work Under anaerobic conditions the pyruvate is reduced to lactate in the course of which only one tenth of the glucose energy is released which is inadequate for cardiac work Furthermore the lactic acid accumulates as an end product in heart muscle and blood

During aerobic metabolism the pyruvate is broken down to high-energy two-carbon active acetate These two-carbon molecules are combined enzymatically with a four carbon molecule oxalacetic acid to yield citric acid Thereafter through the Krebs tricarboxylic or citric acid cycle,[35] with the aid of vitamins and coenzymes two-carbon fragments and their associated hydrogen atoms are removed in steps by oxidative reactions

The released hydrogen does not combine directly with oxygen but is passed on to a series of enzymes (flavoproteins and cytochromes) which act as hydrogen carriers With each step in this series of enzymatic dehydrogenations the energy derived from carbohydrate substrate, now accompanying the detached hydrogen atoms, is released to

each enzyme hydrogen carrier and transferred to phosphate, forming high energy phosphate bond (indicated ~P) The high energy phosphate bond is stored in the muscle fiber after combination with special acceptors notably nucleotide phosphate and creatine The nucleotide adenylic acid combines with one ~P group to form *adenosine diphosphate* (ADP) or with two ~P groups to form *adenosine triphosphate* (ATP) The synthesis of ATP is localized in the mitrochondria (sarcosomes) of the heart muscle cells [31] The combination of creatine with one high-energy phosphate group forms phosphocreatine Phosphocreatine acts as a storage form of ~P and yields its ~P after myocardial contraction to adenosine diphosphate and restores high energy adenosine triphosphate These high-energy phosphate carriers yield their ~P as required for myocardial contraction and relaxation

Muscle Proteins and Myocardial Contraction

Myosin is an elongated fibrous protein conjugate, with a molecular weight of 850 000 usually combined with magnesium, but with a marked capacity to bind other ions such as potassium and calcium The myosin molecule has recently been shown to be composed of four thin, elongated and relatively light (L) meromyosin molecules, strung together lengthwise in series and two shorter and heavier (H) meromyosin molecules lying beside the end L-meromyosin molecules Muscular contraction or shortening appears to be due to the folding of the thin and elongated L-meromyosins, which are sensitive to small changes in ionic concentration Potassium ions form a positively charged atmosphere which causes the ends of the myosin fibril to repel each other and therefore the fiber to remain straight and extended The H molecules of the myosin complex serve as an anchor have a strong affinity for magnesium and adenosine triphosphate and link the myosin to actin The ATPase activity of myosin is due to the H meromyosin

Actin exists as a "globular' protein colloid G actin, with a molecular weight of 57,000 and as a polymerized "fibrous' protein F actin Most of the calcium in the muscle is probably bound to actin G actin is unstable and in the presence of low salt concentrations (e g, 0 1 M KCl), myosin causes its rapid polymerization to threads of F actin Magnesium and ATP appear to be essential for this actin G F transformation The ATP is dephosphorylated to ADP in the course of this polymerization, yielding a high energy phosphate bond to the actin molecules The polymerization of actin is apparently an essential chemical reaction in the contraction process, and occurs prior to or during the rise of tension and coincidentally with the initial heat production The contraction of 1 gm of muscle is accompanied by a breakdown (dephosphorylation) of 0 5 μM of adenosine triphosphate

Myocardial Contraction [44] ■ [60] [19] ■ The following abbreviated summary of the process of muscular contraction has many points of uncertainty due to gaps in our knowledge but represents the essential features of the hypothesis as formulated by Szent Gyorgy and his associates

Prior to systole, F actin and myosin exist in muscle dissociated from each other While attracted by colloidal forces, they are repelled and kept apart by the potassium ions present in muscle cells The cell membrane is polarized The linked meromysin molecules are straight i e, unfolded

The excitatory impulse initiated at the sinoauricular node depolarizes the cell membrane and causes it to become permeable to ions, notably potassium There is an egress of potassium ions with a reduction in the potassium gradient The reduction in muscle cell potassium concentration now permits the union of actin and myosin to form very long molecules of viscous, doubly refractile strings of actomyosin This precipitation of myosin by actin is an example of the method by which a charged protein is discharged

Following *membrane depolarization* and *reduction in cellular potassium* the ATP becomes adsorbed onto myosin and the combined actomyosin is actually an actomyosin ATP complex The presence and concentration of potassium magnesium calcium and perhaps other ions and the pH, are important in the regulation of this reaction and subsequent contraction The linkage of ATP to actomyosin gives the actomyosin tensile strength and somehow makes the meromyosin joints more pliable permitting folding of the muscle protein

Either the actomyosin, as a magnesium complex, or some other substance in muscle acts as an ATP phosphatase so that a *high-energy phosphate bond is split off the ATP* and

supplies the actomyosin fiber with energy for contraction Adenosine diphosphate is the residual of the split ATP molecule[33] About one tenth of the ATP may be converted into a new component, nucleotide II[34]

The charged actomyosin ATP or ADP complex first contracts isometrically increasing the tension of the elastic portion of the muscle fiber, then *shortens maximally* as the elongated molecules fold on each other The actomyosin complex becomes discharged with shortening its energy being partly converted into work performed by contraction, the remainder of its energy being dissipated as heat

Relaxation includes the following processes

1 Potassium reenters the cell and the cell membrane becomes polarized

2 ATP is regenerated from ADP and its high-energy phosphate bone is restored chiefly by the labile ~P obtained in the enzymatic oxidations of glucose, glycogen lactic and pyruvic acids This depends on a continuous oxygen supply In the absence of such a supply or when it is temporarily inadequate as during severe physical exertion and until adequate labile ~P becomes available the high-energy phosphate bond required to regenerate ATP from ADP is supplied by phosphocreatine which is the most important storage form of high-energy phosphate The creatine that is left regenerates phosphocreatine by accepting high-energy phosphate bonds as a result of carbohydrate oxidations

3 Actomyosin is separated from ATP and actin is dissociated from myosin because of the increase in potassium concentration and restoration of ionic equilibrium Perhaps actin F is transformed back to actin G A soluble muscle protein *(the Marsh factor)* in the presence of adenosine triphosphate may be important in causing relaxation[41 2]

4 The folded shortened actomyosin threads, having been discharged now become recharged unfold and become straightened Elongation may also result from its elastic property

Cardiac Muscle Metabolism and Heart Failure

From the physiologist's viewpoint cardiac fatigue or cardiac failure is characterized by an inadequacy of cardiac capacity to perform work relative to the load imposed upon the heart Or more practically the blood supply provided by the contracting heart is inadequate for the demands of the tissues throughout their ordinary range of activities It would be of the utmost value to know, at least as an early step toward progress what is the chemical physiologic basis of heart fatigue and failure in terms of the various steps in the metabolism and energetics of cardiac contraction and restoration

From this viewpoint cardiac failure may be related to (1) an inadequacy of the raw materials forming the substrate needed to produce high-energy bond phosphate or a deficiency in the generation of such (2) an inadequacy of muscle or muscle proteins required for contraction or (3) an impairment in the utilization of this energy for muscular contraction and its transformation to useful work

1 An inadequacy of raw materials to generate energy is rarely responsible for clinical heart failure except possibly in unusual cases of prolonged dietary deficiency Lack of accessory materials notably enzymes and coenzymes occasionally is associated with heart failure This probably applies to beriberi heart disease in which thiamine inadequacy is responsible for deficiency of the coenzyme cocarboxylase which is concerned in the oxidation of pyruvate to active acetate (acetyl coenzyme A) Consequently there is an interruption in the oxidative processes which produce the energy needed for myocardial contraction Lack of oxygen is the most obvious factor which may be responsible for heart failure by reducing or eliminating the aerobic metabolic processes which generate most of the needed energy Wohl et al[33] found a significantly lower concentration of thiamine and cocarboxylase in the hearts of patients who died of congestive heart failure (not due to beriberi) than in the hearts of those who died of other causes

Actually the relation of oxygen lack to clinical heart failure is not clear cut The two commonest diseases associated with heart failure are hypertension and coronary atherosclerosis In the former oxygen lack plays a part only insofar as the associated cardiac enlargement imposes a theoretical disadvantage to oxygen diffusion in the myocardial fiber but as we have seen experimental evidence indicates that there is no deficiency in energy production in the enlarged heart In coronary heart disease oxygen lack is more distinctly associated with pain than with heart failure Severe anemia is the most direct example of oxygen deficiency as a factor in

heart failure, but as a rule anemia induces heart failure only in the presence of intrinsic heart disease. Hyperthyroidism, too, has been regarded as an indirect cause of oxygen lack, i.e., relative to the high level of myocardial as well as general tissue metabolism. Hyperthyroidism rarely, if ever, causes heart failure unless there is associated cardiac disease. Thus it is difficult to correlate the vast majority of cases of heart failure with any impairment of energy production due to lack of the common foodstuff substrates of enzymes and coenzymes or even of oxygen.

Cases of heart failure due to anemia, thiamine deficiency and hyperthyroidism have in common the incomplete oxidation of carbohydrate with consequent accumulation of lactic and pyruvic acids which cause peripheral vasodilatation. These cases also have in common an absolute high cardiac output despite heart failure, albeit the high output is insufficient for cardiac needs. High output failure may thus be regarded as the form of heart failure due to impairment of energy production. However, it is improbable that the latter is the sole or even major cause of the heart failure because (a) there is almost always associated cardiac disease of other etiology, (b) the high cardiac output and therefore the increased work of the heart result not from the effects of incomplete oxygenation and accumulation of acid metabolites in the myocardium, but from these effects on peripheral tissues and (c) the same type of high output failure is observed in the purely mechanical arteriovenous fistula in which there is no question of impaired myocardial energy production. The vasodilatation in anemia, beriberi and hyperthyroidism may be regarded as producing the equivalent of an arteriovenous shunt, and the heart failure, as in traumatic arteriovenous fistula, may result from the effects of the increased load on the heart.

2. An inadequacy of contractile substance, namely actomyosin or its precursor proteins, can rarely be considered as the cause of heart failure. Such a causative relationship may apply to occasional instances of diphtheritic myocarditis with extensive muscle degeneration and necrosis, and perhaps to some cases of multiple coronary occlusions with extensive myocardial necrosis and replacement fibrosis. However, extracts of homogenized cardiac muscle from dogs with experimental chronic heart failure showed a decreased concentration and viscosity of actomyosin and a decreased viscosity response on addition of ATP in comparison with similar muscle extracts from normal dogs.[4] These and related studies suggested that in the failing myocardium actomyosin is found in a partially dissociated (depolymerized) state.

Thus heart failure may be due to a physicochemical change in the character of actomyosin rather than in an inadequate amount of the protein. The physical or molecular structure of myosin or actomyosin is probably of great importance in the performance of mechanical work during contraction of the myofibril. In experimental heart failure in the dog there were noted marked changes in the physicochemical properties of cardiac myosin which were consistent with a considerable increase in molecular weight.[48, 47a] The effect of purely mechanical stresses in inducing cardiac failure also suggests that physical changes in the structure of the contracting muscle protein may be important.

3. A defect in the utilization of energy, either because of impairment in the transfer of high-energy phosphate bonds to actomyosin or an impairment in the conversion of this energy to useful work, appears to be the most likely physical-chemical basis of the common forms of heart failure associated with cardiac enlargement, such as hypertension and rheumatic cardiovalvular disease. This is based on the failure to find adequate evidence for a deficiency in energy production either in studies with the heart lung preparation or in studies of coronary sinus catheterization in humans which showed that oxygen extraction and substrate utilization were essentially normal in the enlarged and failing heart. Since the cardiac output was diminished when oxygen utilization was normal, it appeared that there was impairment not in energy production but in conversion of this energy to useful work. The possible relation of disturbances in cationic concentrations, particularly intracellular potassium and sodium, to this impairment in the transfer and utilization of energy is discussed on page 136. A defect in the utilization of energy to produce useful work may be due to changes in the physicochemical structure of actomyosin as suggested above, or to disturbances in enzyme content or structure, e.g., the relative content and speed of interconversion of the monomeric and dimeric forms of phosphorylase

Disturbances of the Glycogen Cycle The concentration of glycogen in the myocardium is a constant with normal activity and even with hypoglycemia. Myocardial glycogen is depleted only with complete anoxia and with epinephrine. On the other hand it may actually rise with starvation and with diabetic ketosis presumably because lipids and ketone bodies are utilized and carbohydrates spared[27, 8]. There is evidence that relative anoxemia present in the hypertrophied and failing heart interferes with the aerobic oxygenation of lactic and pyruvic acid and the consequent energy formation required for muscular contraction. Studies of experimental anoxemia[20] and coronary occlusion[30] revealed a reduction of cardiac glycogen especially in infarcted areas, and an accumulation of lactic acid in blood and muscle. Herrmann and Decherd[7] found a similar loss of glycogen in the infarcted areas of human hearts. Other observers have stressed the finding of increased lactic acid in the blood of patients with congestive heart failure[42] particularly because of experimental evidence that the mammalian heart is much more readily exhausted by the accumulation of lactic acid than is skeletal muscle[50]. However it is more probable that increased blood lactic acid is the result and not the cause of cardiac failure. A rise in the pyruvic acid concentration of the blood has been found in patients with congestive heart failure[65]; it probably has the same significance as the rise in lactic acid.

Disturbances of Phosphocreatine Metabolism The fact that phosphocreatine is an *immediate* source of energy for muscular contraction and that it is reduced in skeletal muscle in certain forms of myasthenia and muscular dystrophies suggests that cardiac fatigue and failure may be due to a loss of myocardial phosphocreatine or to a disturbance in its metabolism. Since phosphocreatine is a very labile compound it cannot be determined directly at autopsy; but creatine concentration was taken as a measure of its quantity during life. A higher creatine concentration has been found in the left than in the right ventricle and this has been correlated with the greater strength of contraction of the former[55]. However the difference in creatine concentration may be insignificant if allowance is made for the greater amount of extracellular water, fat and connective tissue in the right ventricle.

With slight increments in heart weight the creatine concentration was found to increase but with progressive cardiac hypertrophy there was a corresponding reduction in creatine[47]. In hearts of persons dying of congestive heart failure a substantial diminution in the cardiac creatine concentration has been uniformly observed[32, 40]. In cases of cor pulmonale the creatine concentration has been reported to be reduced in the right ventricle but not in the left[40]. The observed reductions in cardiac creatine in heart failure, like those of glycogen, have been related to deficient oxygenation, for similar low values for creatine in heart muscle have been found following asphyxia and myocardial infarction due to coronary artery occlusion[3]. However there is considerable doubt whether determinations of total creatine post mortem can be used as a measure of phosphocreatine during life. For there is experimental evidence based on simultaneous determination of myocardial creatine and phosphocreatine that there is a poor correlation between total creatine and phosphocreatine concentrations[47].

Phosphorus Metabolism Phosphorus concentrations in cardiac muscle have also been found to be reduced in congestive heart failure[6]. The total phosphorus in the heart consists of an acid soluble fraction (soluble in 5 per cent trichloracetic acid) and an acid insoluble fraction. The acid soluble fraction comprises the so-called activity substances including phosphocreatine, hexosephosphate, adenosine triphosphoric acids, all important in muscular contraction. It is this acid soluble phosphorus fraction which accounts chiefly or entirely for the reduction in cardiac phosphorus in heart failure[16].

The acid insoluble phosphorus fraction consists of lipids or phosphatids. Various observers have noted a reduction in myocardial lipids in the fatigued experimental heart and in the hearts of persons dying of heart failure. However there is some doubt as to whether the reduction in cardiac lipids is statistically significant. Theoretic importance has been attached to the cardiac lipids because of their higher concentration in cardiac than in skeletal muscle and because of their active role in surface phenomena.

Adenosine Triphosphoric Acid A reduction in adenosine triphosphoric acid in the hearts of patients dying of congestive heart failure

has been revealed indirectly by determination of the nitrogen of the purines convertible to oxypurines.[40] The fact that the reduction of potassium and phosphorus exceeds the reduction in heart muscle creatine suggests also that this difference is due to a concomitant loss of adenosine triphosphoric acid, which like phosphocreatine contains phosphorus and is combined with potassium. The fact that dephosphorylation of ATP takes place in the heart after its removal from the body indicates that the determination of easily hydrolyzable phosphate, as often done to measure ATP, would lead to underestimation of this nucleotide.[34]

Potassium and Sodium. The important role of potassium in the contraction of heart muscle has been discussed. Recent evidence suggests that disturbances in intracellular as well as extracellular potassium may be of importance in the impairment of cardiac contraction associated with heart failure. Extracellular sodium is a key factor in producing the *clinical features* of congestive heart failure (Chapter 7). But intracellular sodium, like intracellular potassium, may be concerned with the fundamental chemical disturbances which are the primary basis for inefficient cardiac contraction and cardiac failure. Although the employment of radioisotopes of potassium and sodium has helped in the estimation of these intracellular ions, highly satisfactory methods for this purpose are not available. The difficulty of determining intracellular potassium and sodium is enhanced in the presence of congestive heart failure.

Studies of tissues at autopsy indicated that the potassium concentration of heart muscle was diminished. Recent studies of this type confirmed the reduction in myocardial potassium concentration and indicated that this reduction was not due to heart muscle edema, as the total water content of normal hearts and those from patients dying of congestive heart failure was the same.[1, 2] Furthermore it was found that the reduction in potassium concentration in dried heart tissue was accompanied by a similar increase in sodium concentration in hearts that had failed and that the sum of potassium and sodium remained the same in normal and failing hearts. There was indirect evidence also that the beneficial effect of digitalis was related to its normalizing influence on myocardial electrolyte balance.

The concentrations of potassium and sodium appear to have an important influence on the phosphorylation of AMP (adenosine monophosphate) and ADP (adenosine diphosphate) to ATP and on the phosphorylation of creatine to phosphocreatine, the steps by which energy produced in cardiac metabolism is transferred for later utilization in contraction. Phosphorylation of creatine is stimulated by potassium and is optimum at potassium ion concentrations of about 50 to 200 mEq./liter,[10] while the average body intracellular concentration of potassium is 112 mEq./liter.[15] Significant reductions in myocardial potassium concentration, as suggested by the above-mentioned studies, might seriously impair this important process of energy transfer. Conversely, increased intracellular sodium ion concentration interferes with the transfer of high energy phosphate to creatine and the conversion of AMP and ADP to ATP with a similar transfer of energy.[8] Sodium ion concentrations of 35 mEq./liter or more have such an inhibitory effect. Since the average intracellular sodium concentration for the body as a whole is about 37 mEq./liter,[15] a relatively slight increase in myocardial cellular sodium would significantly interfere with energy transfer and myocardial contraction, assuming that intracellular myocardial sodium did not vary much from the body average intracellular sodium. There is also evidence that the force of myocardial contraction is dependent on the *total quantity* of sodium and potassium within the muscle fiber.[60, 61] Present-day theory of myocardial contraction assumes that the egress of potassium out of the myocardial cell (and the inflow of sodium ion) is an essential feature of depolarization as well as of the formation of the actomyosin ATP complex necessary for cardiac contraction. If heart failure is associated with low intracellular potassium and elevated intracellular myocardial sodium, the disturbance in ionic intracellular-extracellular gradient might interfere with these processes of depolarization and contraction. They would also suggest some disturbance in the intracellular mechanisms controlling sodium potassium concentrations in congestive heart failure.

In summary, chemical studies of hearts of individuals who had died of heart failure indicate significant changes in those substances which are now considered of fundamental

importance in muscular contraction There is indirect evidence of a loss of myocardial glycogen and direct evidence of a reduction in myocardial creatine total and acid soluble phosphorus compounds potassium and possibly lipid and an increase in intracellular sodium The significance of these findings is somewhat uncertain in view of the questionable reliability or indirectness of the methods employed and because of possible doubt as to the applicability of studies of myocardial tissues post mortem and of in vitro studies to living myocardium

PRECIPITATING CLINICAL CAUSES OF CONGESTIVE HEART FAILURE

While the fundamental cause for the onset of congestive heart failure is still obscure a clinical precipitating factor can often be determined Of 100 cases of cardiac failure studied by Sodeman and Burch[47] failure was precipitated by some demonstrable factor in 53 while in 47 it developed gradually without apparent cause

1 Infections

Myocardial failure in the cardiac patient is very often precipitated by (a) infections which directly increase the myocardial disease or (b) intercurrent infections which incidentally impair cardiac function or otherwise induce heart failure

(a) Rheumatic fever is the prime example of a disease related to infection which may cause cardiac failure by direct action on the heart Rheumatic fever is the commonest cause of cardiac failure between the ages of 10 and 40 The onset of heart failure after a more or less prolonged period of inactive rheumatic heart disease has been frequently attributed to recurrent rheumatic activity The studies of Rothschild Kugel and Gross[52] on 161 rheumatic hearts of persons who had died of congestive heart failure showed that up to the age of 20 95 to 100 per cent of the hearts revealed signs of active rheumatic carditis between the ages of 20 and 40 about 75 per cent disclosed such signs and even after the age of 40 cardiac failure was associated with active rheumatic myocardial lesions in one fourth of the cases Biopsies of left atrial appendages from patients subjected to mitral commissurotomy for severe mitral stenosis revealed a high incidence of lesions regarded as signifying active rheumatic inflammation

Nevertheless in adult life certain other factors seem more important than rheumatic activity in the precipitation of heart failure in rheumatic hearts The pathologic and biopsy studies indicating the presence of Aschoff bodies do not denote a corresponding, clinically significant rheumatic activity

(b) Intercurrent infections especially those of the respiratory tract very often lead to the development of congestive heart failure but usually only in patients with preexistent chronic cardiac disease It should also be emphasized that upper respiratory infections predispose to attacks of rheumatic fever and thus indirectly may cause cardiac failure Subacute bacterial endocarditis is not infrequently complicated by congestive cardiac failure either because of increased valvular deformity or destruction and myocardial damage

The mechanisms by which infections especially respiratory infections may induce cardiac failure are (1) Increased work of the heart due to fever and tachycardia (2) Toxic effect on the myocardium which is not demonstrable anatomically (3) Diminution of the diastolic period of recovery because of tachycardia This factor is particularly harmful in the hypertrophied heart (4) Cough in respiratory infections may represent intense muscular exertion and a severe strain on the heart in persons with cardiac disease (5) Infections may be associated with impairment of renal excretion of sodium

2 Inadequate Coronary Blood Flow (p 129)

We have already discussed the theoretical importance of a diminished coronary blood flow in causing cardiac failure In emphasizing that it is usually the large heart which fails we considered the relatively inadequate coronary blood flow and impaired diffusion of oxygen to the hypertrophied fibers and the effect of the resulting anoxemia on cardiac metabolism We often observe the cardiac patient who remains well compensated until coronary artery disease develops in middle or old age In rheumatic cardiovalvular disease in hypertension and in luetic aortic insufficiency cardiac failure often develops only when coronary atherosclerosis (narrowing or occlusion) adds its baneful influence to that of valvular or cardiovascular disease In these cases the cardiac hypertrophy is an effective compensatory mechanism until coronary insufficiency interferes with the increased needs for oxygen In addition acute coronary oc

clusion, by causing extensive damage to heart muscle, may precipitate failure in a heart which was not previously enlarged

3 Changes in Rate and Rhythm

Paroxysmal tachycardia, in which the heart rate is often 200 per minute or more occasionally precipitates congestive heart failure if the attack is prolonged As a rule this occurs in patients with underlying organic heart disease, but occasionally it may occur in the presence of a normal heart In infants and children paroxysmal tachycardia and/or congenital heart disease are the commonest causes of congestive heart failure Rapid ventricular rates (over 100) with atrial fibrillation or atrial flutter often lead to failure of the diseased heart or at least are associated with the onset of cardiac failure Tachycardia interferes with myocardial contraction not only by preventing proper oxygenation in an hypertrophied heart but also when the rate exceeds 180 per minute by seriously reducing the diastolic recovery period and preventing adequate cardiac filling In patients with tight mitral stenosis any factor which induces tachycardia may precipitate acute left atrial failure (pulmonary edema)

4 Excessive sodium intake may precipitate acute left heart failure [redacted] g after several successive meals of high sodium content

5 Discontinuation of digitalis may induce decompensation after cardiac failure had been controlled

6 Pregnancy and Childbirth

Heart failure sometimes develops in the course of childbirth or pregnancy in patients with previous heart disease (Chapter 47) Acute pulmonary edema is occasionally observed in patients with mitral stenosis and pulmonary congestion It is now recognized that in persons with well compensated heart disease, heart failure during pregnancy and childbirth occurs with extreme infrequency On the other hand in patients with previous attacks of heart failure or in those with limited cardiac reserve congestive heart failure occurs commonly

7 Hemorrhage and Anemia

Anemia [redacted] not infrequently associated with cardiac enlargement and sometimes with congestive heart failure In persons with chronic cardiac disease heart failure may be induced by progressive anemia or acute loss of blood I have seen heart failure precipitated in two patients with hypertensive and [redacted]therosclerotic heart disease and in one with rheumatic cardiovalvular disease immediately after an acute hemorrhage due to a peptic gastric or duodenal ulcer I have also seen cardiac failure develop in a patient with hypertensive cardiovascular disease with a hemoglobin of 17 per cent due to a chronic bleeding hemorrhoid These precipitating factors of cardiac failure are important to recognize because they can sometimes be prevented Treatment may beneficially affect the manifestations not only of the anemia but of the heart failure

8 Pulmonary Embolism

I have repeatedly observed cardiac failure induced by pulmonary embolism, especially in patients with rheumatic heart disease In some instances persistence or recurrence of heart failure is related to repeated embolization In many of these cases the precipitation of heart failure [redacted] erroneously attributed to bronchopneumonia

9 Transfusions and Sodium Containing Infusions

These not infrequently precipitate heart failure in patients with organic heart disease and in elderly patients without overt evidence of previous heart disease They may also induce heart failure in patients with acute glomerulonephritis toxemia of pregnancy or toxic nephrosis with severe oliguria or anuria

10 Physical and Emotional Strains

Acute overexertion occasionally initiates congestive heart failure and then only in persons with diseased hearts It [redacted] uncertain to what extent *prolonged* overexertion contributes to the occurrence of heart failure Sodeman and Burch[87] and others list exercise as the most common precipitating factor of cardiac failure, but it is not clear what degree or form of exercise [redacted] responsible or what is the exact relationship to failure Insurance statistics which indicate that long continued and strenuous labor adversely affects the heart fail to account for many associated factors such as differences in constitution, heredity and social and economic status

Occasionally heart failure appears to be precipitated by experiences which involve considerable physical and emotional strain For example pulmonary edema or other evidences of congestive heart failure may appear after surgical operations coitus or prolonged worry and anxiety Surgical operations may lead to coronary insufficiency or myocardial infarction with subsequent heart failure as [redacted]

result of a fall in blood pressure and shock The tachycardia and elevation of blood pressure may be the factors responsible for heart failure after coitus In both of these as well as in various states of fear and anger the cardiac output and work of the heart may be increased

11 Environmental Heat and Humidity

A rapid elevation in atmospheric temperature and humidity may precipitate acute left ventricular failure in subjects with cardiac disease and diminished cardiac reserve Impaired dissipation of heat causes marked vasodilatation of superficial vessels with increase in cardiac rate and speed of the circulation thereby augmenting the venous return and load on the heart[5]

SIGNIFICANCE OF THE PRECIPITATING CAUSES OF CONGESTIVE CARDIAC FAILURE

It is important to recognize the *precipitating* causes of heart failure for we can more readily avoid or eliminate these causes than we can other factors in the development of heart failure For the present the avoidance of these precipitating factors offers the most direct and the most promising approach to the prevention or postponement of heart failure The fundamental basis of heart failure is still obscure while the underlying causes are usually not susceptible either of prevention or treatment

Recognition of the precipitating cause of cardiac failure is important in the prognosis as well as treatment of this condition Sodeman and Burch[57] found that of 47 cases of cardiac failure without detectable precipitating cause 46 were unable to restore cardiac compensation despite treatment On the other hand of 54 cases with a demonstrable precipitating factor compensation was rapidly established in 40 Thus the outlook in a given case of heart failure is much better when a definite precipitating factor is present

UNDERLYING CAUSES OF CONGESTIVE HEART FAILURE

For practical as well as theoretical reasons we have segregated the fundamental cause the precipitating causes and the underlying causes of congestive heart failure In considering the fundamental cause we attempted to investigate the *mechanism* or bridge by which the diseased and occasionally the normal heart becomes the failing heart The precipitating causes include the clinical conditions which because of their close sequential relationship appear to be concerned in the onset of the symptoms of heart failure The underlying causes of heart failure comprise those diseases which injure the pericardium myocardium valves or peripheral vessels and thereby bring about functional and anatomic changes in the heart or vascular system which eventually lead to cardiac failure In other words the underlying causes of heart failure are the various specific forms of cardiovascular *disease* as contrasted with the forms of cardiovascular *failure* These underlying causes are considered in detail in subsequent chapters in this book

Chapter 7

CLINICAL AND PATHOLOGIC FEATURES OF CHRONIC (CONGESTIVE) HEART FAILURE

Congestive heart failure is essentially a *clinical* syndrome From the physiologic viewpoint heart failure represents an inability of the heart to maintain an adequate output But it is difficult to measure this disability in clinical practice Furthermore because of compensatory mechanisms the cardiac output may sometimes remain normal despite the presence of heart failure (Chapter 8) The manifestations of congestive heart failure are only exceptionally directly due to an inadequate cardiac output, as a rule they are the consequences of the compensatory mechanisms Congestive heart failure is defined and recognized by the presence of distinctive clinical features which are the subject of this chapter

LEFT SIDED HEART FAILURE

While the normal heart appears to act as a single pump the left and right chambers are really distinct anatomic and functional entities Under pathologic circumstances one side or even one chamber of the heart may fail while the other side is still functioning normally Sooner or later failure of one side of the heart places a strain on the remainder which eventually leads to generalized cardiac failure but for a variable period isolated left sided or isolated right sided heart failure may exist as a distinct and independent clinical syndrome

Failure of the left side of the heart is the most important and most common form of congestive heart failure encountered in medical practice The existence the pathogenesis and the clinical features of left sided heart failure were noted by Hope[38] and by a succession of French physicians [51] In recent years the importance of the syndrome of left ventricular failure was stressed and its clinical features described in this country by Pratt [84] White [104] Weiss and Robb [102] and others in France by Gallavardin[32] and by Lutembacher[53] and in England by Bedford [8]

CAUSES OF LEFT SIDED HEART FAILURE

Left ventricular failure results from those cardiovascular diseases which injure or strain the left ventricle, namely hypertension coronary artery disease aortic valvular disease and mitral regurgitation Rarely there are other causes In children acute rheumatic myocarditis and congenital cardiac lesions are the commonest causes of heart failure Bedford[8] observed 154 cases of left ventricular failure in 132 of which the failure was paroxysmal and in 22 persistent or terminal In the group of 132 111 patients suffered from hypertension associated in 43 with angina pectoris or coronary thrombosis 12 patients suffered from coronary disease without hypertension 21 suffered from aortic valvular disease There were only a few cases of syphilitic aortic insufficiency

Left atrial failure results from mitral stenosis which is almost invariably caused by rheumatic heart disease Mitral regurgitation causes both left ventricular and left atrial failure It is seen among earlier age groups than is left ventricular failure Left atrial failure is seen predominantly among females and left ventricular failure among males These and other factors in the etiology of left sided heart failure are related not to the heart failure itself but to underlying causative diseases For this reason details as to etiology should be sought in the chapters devoted to these diseases

PATHOLOGIC PHYSIOLOGY OF LEFT SIDED HEART FAILURE

The pathogenesis of heart failure and its pathologic physiology will be discussed in Chapter 8 The pathogenesis of *left sided*

heart failure is discussed on page 184 The pathogenesis of the individual symptoms is discussed in Chapter 9

Most of the manifestations of left sided heart failure result from the increased pulmonary blood volume and consequent engorgement of the lungs and from increased pulmonary capillary pressure (Chapter 9) Among the resulting physiologic disturbances are the rigidity and loss of elasticity which interfere with normal inspiratory and expiratory movements, reduction in vital capacity impairment of diffusion of oxygen and slowing of the pulmonary circulation The last is partly beneficial because it compensates for impaired diffusion by permitting a longer period for each unit of blood to absorb oxygen and release carbon dioxide

PATHOLOGY OF LEFT SIDED HEART FAILURE

The pathology of left sided heart failure is essentially the pathology of engorged lungs (passive congestion of the lungs) The lungs appear somewhat different when the engorgement results from left ventricular failure in hypertensive, coronary artery or aortic valvular disease than when it results from left atrial failure in cases of mitral stenosis The differences are due to the more gradual development and the much longer duration of the pulmonary engorgement with mitral stenosis The latter is described in detail in the chapter on mitral stenosis (p 26)

The lungs in left-sided heart failure are usually larger and firmer than normal, and do not collapse readily when the chest wall is opened because of increased content of blood and therefore diminished elasticity In cases of left ventricular failure the lung is usually dark red and "wet" in that bloody or frothy fluid may be expressed easily by squeezing or scraping of the surface or by cutting into the lung In cases of longstanding pulmonary congestion, e g, in mitral stenosis the lung is usually dry and indurated due to fibrosis and brown due to deposition of hemosiderin following phagocytosis of extravasated erythrocytes (brown induration of the lungs)

Microscopically[61] the lungs reveal engorgement and widening of capillaries with encroachment on alveoli, thickening of alveolar septa, extravasation of large mononuclear cells (heart failure cells) containing erythrocytes or the reddish granules of the iron pigment, hemosiderin

Other frequent findings in the lungs, besides pulmonary congestion and pulmonary edema, include pulmonary *emboli and infarcts hemorrhages*, hypostatic congestion, *bronchopneumonia* and bronchitis atelectasis and hydrothorax or pleural effusion There may be miliary, nodular aggregates of macrophages containing hemosiderin (p 643) The *pulmonary vessels* show medial hypertrophy and some intimal hyperplasia and fibrosis of the muscular arteries probably related to increased pulmonary vascular pressure[96a]

CLINICAL FEATURES OF LEFT SIDED HEART FAILURE

Symptoms

Exertional Dyspnea and Dyspnea at Rest Dyspnea (breathlessness, shortness of breath) denotes the subjective respiratory distress associated with increased effort in breathing When mild it may be purely subjective and discovered only by specific inquiry or from the patient's voluntary complaint When more severe there may be objective evidence of increased respiratory effort such as interrupted breathless speech, frequent stops during walking or climbing stairs dilatation of the alae nasi or, when very severe the use of the accessory muscles of respiration

Dyspnea during ordinary exertion is usually the earliest symptom of left-sided heart failure The dyspnea may be minimal in the morning and may progress gradually until it is quite disturbing by the time the patient retires at night (evening dyspnea[17]) At first dyspnea occurs only with moderately severe exertions such as running for a bus or train walking up a hill or climbing several flights of stairs Gradually, or more rapidly (e g, after an infection or coronary occlusion), the dyspnea becomes more severe and appears with less and less strenuous activity The patient then experiences breathlessness even when walking along level ground and is compelled to rest frequently in order to get his breath Finally dyspnea may persist even when the patient is at rest in bed

Of interest is the frequent alleviation of dyspnea when the right heart also fails Conversely in combined right- and left-sided heart failure the administration of digitalis and diuretics sometimes leads to an initial intensification of dyspnea as the mobilization of edema fluid and right ventricular improve-

ment lead to an augmented output into the pulmonary vascular tree

The subjective nature of mild dyspnea sometimes makes it difficult to evaluate Cardiac dyspnea is of a panting or puffing quality and not merely an "inability to take a deep breath The latter sometimes characterized as sighing respiration, is often of psychic origin Objectively cardiac dyspnea is characterized by rapid, shallow respirations in contrast with the deep breathing of diabetic or uremic acidosis The total ventilation per minute (rate times depth) is increased [64] The increase in ventilation is proportionately greater than the increase in oxygen consumption [64] When dyspnea is caused by heart failure it is precipitated by exertions previously performed without discomfort Factors such as increasing obesity, change to sedentary occupation, pregnancy, pulmonary disease etc, must be excluded

Pathogenesis of Dyspnea (see p 189)

Orthopnea Orthopnea is the form of dyspnea which occurs when the patient assumes a recumbent position To avoid respiratory distress on going to bed he elevates the head and chest with two or three pillows Sometimes he unconsciously adopts a semi sitting position while asleep When the orthopnea is severe the patient may have to be propped straight up in bed or he may obtain comfort only by sitting at the edge of the bed with his feet hanging, often his head and neck are flexed forward and his hands clutch the side of the mattress in order to aid the accessory muscles of respiration He may spend most or all of the night in a chair because this offers the best support and the least recumbency

These positions tend to relieve orthopnea by diminishing pulmonary congestion and improving pulmonary ventilation (p 191) In patients with continuous dyspnea and orthopnea breathlessness persists even after sitting up but it is usually less intense than in the recumbent position In some persons orthopnea occurs in one recumbent position (e g the left lateral) but not in another (e g the right lateral) This selective type of orthopnea, which has been termed trepopnea [103] is probably the result of greater pulmonary engorgement in the first position than in the other

Orthopnea may be noted at night in persons who have suffered no exertional dyspnea during the day I have seen patients with valvular heart disease who have had to sleep on two or three pillows at night because of orthopnea and yet continued for several years to conduct their business during the day without noticeable dyspnea

Pathogenesis of Orthopnea (see p 194)

Paroxysmal Dyspnea Paroxysmal dyspnea refers to the respiratory distress which appears in attacks without apparent cause Because such attacks usually occur at night after the patient has fallen asleep they are often called paroxysmal nocturnal dyspnea The term *cardiac asthma* is employed synonymously with paroxysmal dyspnea because the wheezing character of the respiration and the signs in the lungs resemble those in bronchial asthma Paroxysmal dyspnea usually occurs in patients who are suffering also from exertional dyspnea and from orthopnea Occasionally persons who are fairly comfortable and have little or no dyspnea during ordinary activity by day are intensely distressed by nocturnal dyspnea

The *attack of paroxysmal dyspnea* almost invariably occurs about an hour or two after the patient has retired and fallen asleep Diurnal attacks also occur while the patient is asleep The *precipitating cause* of the attack is uncertain and probably variable Cough bad dreams slipping of the patient from his pillows to a more recumbent position, turning to the side on which he is ordinarily dyspneic abdominal distention are among those suggested

The attack varies greatly in severity and duration In mild cases the patient awakens with a sense of respiratory distress or suffocation often associated with anxiety To obtain comfort he may merely sit up in bed or sit at the edge of the bed with his feet hanging In other instances the patient pleads to have the windows opened further or sits in a chair beside the open window because of the mistaken feeling that there is insufficient air in the room In the mildest cases relief is obtained a few minutes after sitting up Often the attack ends immediately after coughing up and expectorating blood tinged mucus In the less mild cases relief may not occur for half an hour to an hour In the relatively mild cases the physician may not be summoned at all or the attack may have subsided by the time the physician arrives

In severe attacks of paroxysmal nocturnal

dyspnea, the respiratory distress is much more intense and prolonged. The patient is found sitting upright in bed trying desperately to get more air by the use of the accessory muscles of respiration. The breathing is rapid. Sometimes it is noisy due either to audible asthmatic wheezes[83] or to bubbling or gurgling sounds caused by moisture in the lungs. As a rule the respiration is regular, but *it may have periodic variations. Occasionally* attacks follow each other in rapid succession—a cardiac form of status asthmaticus. The attack usually yields dramatically to a hypodermic injection of morphine and other therapeutic measures (see p. 292). The next morning the patient may feel as well as before the attack but more often he is exhausted and breathless. Occasionally a severe or protracted attack of paroxysmal nocturnal dyspnea ends fatally, usually with the development of extensive pulmonary edema. During the attack the circulation time is prolonged,[9] the pulmonary artery and capillary pressure are increased[49] and the systemic venous and right atrial pressure are increased,[85, 49] except in the presence of shock. The vital capacity is diminished.[102, 80] The arterial blood oxygen is often diminished,[79] but Vitale and associates[100] found an arterial oxygen saturation greater than 93 per cent in 7 of 12 patients with acute pulmonary edema.

Pathogenesis of Paroxysmal Dyspnea (see p. 195).

Pulmonary Edema. Clinical manifestations of pulmonary edema are usually observed in patients suffering from cardiac asthma. Often pulmonary edema accompanies or complicates the attacks of paroxysmal dyspnea. But it may appear for the first time in persons who have never experienced any form of dyspnea, e.g., after an attack of coronary artery occlusion, an hypertensive crisis, after exertion in patients with mitral stenosis, or after transfusions or intravenous infusions.[[illegible], 94] A slight degree of pulmonary edema is probably present during most attacks of cardiac asthma, but a characteristic clinical picture is produced only with massive edema of the lungs. Repeated nocturnal attacks of acute pulmonary edema may occur in patients who are asymptomatic and carry out normal activity and work during the day. Between attacks there may be no symptoms or signs of heart failure. Like cardiac asthma, pulmonary edema usually occurs in patients with left ventricular failure secondary to coronary artery disease (especially coronary occlusion), hypertension and aortic valvular disease. Pulmonary edema occurs less commonly with mitral stenosis, usually as a complication of pregnancy or labor, undue physical exertion, sexual intercourse, tachycardia or a pneumonic infection.

The clinical picture of acute pulmonary edema[46] is characterized by intense dyspnea, orthopnea, cough and extreme anxiety. The breathing is always noisy either because of loud inspiratory and expiratory wheezes or audible gurgling or bubbling sounds. There is always a fair amount of sputum but in severe attacks the patient drowns in the profuse secretions which may pour from the nose as well as the mouth. The sputum is usually frothy and may be colorless, but as a rule it is pink stained because of the presence of blood. The sputum is unusually rich in protein, the concentration of which may be as high as [illegible] to 3 per cent.

The patient is cyanotic, especially if the attack is prolonged, and often his skin is covered by a cold sweat. He may suffer from intense precordial oppression or actual pain. The blood pressure is usually elevated unless there is shock. The pulse is full but if relief is not obtained it becomes rapid and thready. As in cardiac asthma, the physical signs may resemble those of intense pulmonary emphysema. But whereas with cardiac asthma there may be no râles or sonorous, sibilant or crepitant rales at the extreme bases of the lungs, with definite pulmonary edema there are moist subcrepitant rales over extensive areas or throughout the lungs anteriorly and posteriorly. There are often also coarse bubbling râles which may be heard even without examining the patient.

The attack of pulmonary edema may be relatively mild or very severe. It usually subsides spontaneously after a few minutes or hours, often following the coughing up of some blood-stained frothy sputum. Frequently the attack is dramatically and rapidly controlled by an injection of morphine, the application of tourniquets to the extremities or a generous venesection. *Except for temporary exhaustion,* the patient is usually rapidly restored to the same condition as before the attack. While any given attack usually subsides spontaneously or with treatment, acute pulmonary edema

may end fatally in its first or some subsequent episode

Pathogenesis of Pulmonary Edema (see p 196)

Cheyne Stokes Respiration This is a periodic form of breathing characterized by waxing and waning of the depth of respiration and by regularly recurrent periods of apnea [17, 18] Left ventricular failure is most likely to be associated with Cheyne-Stokes respiration when it occurs in elderly persons with hypertension and cerebral arteriosclerosis who have received opiates or large doses of sedatives It may appear in association with the Stokes Adams syndrome It is not a specific symptom of heart failure and occurs in a variety of cerebral diseases Biot respiration, which is seen in patients with increased intracranial pressure is distinguished by identical depth of each respiration, irregular respiratory periods and only four or five breaths to each period [18]

In the typical Cheyne-Stokes respiration several hardly perceptible shallow respirations gradually and rhythmically deepen into respiratory excursions of normal depth After a half dozen such the respirations become deeper and deeper until they are abnormally exaggerated following which they again gradually subside until they are hardly perceptible This respiratory cycle comprising thirty or more respirations consists of phases of crescendo and diminuendo which occupy one to three minutes Often the shallow respirations shade off into a period of apnea which may last ten to thirty seconds or longer Prolonged apneic periods may be associated with deepening cyanosis and muscular twitchings of the face and extremities Cheyne-Stokes respiration may be accompanied by periodic changes in cardiac rhythm including sinus slowing nodal rhythm and various degrees of heart block

Pathogenesis of Cheyne-Stokes Respiration (see p 198)

Cough Cough is almost invariably present with the acute paroxysms of dyspnea and with pulmonary edema in patients with left sided heart failure It may also be a significant symptom in the intervals between such attacks It is often worst at night or occurs only at that time Insomnia may be due to the cough Sometimes the cough of heart failure like dyspnea may be induced only by exertion or recumbency The cough may be secondary to the pulmonary engorgement, to chronic congestion of the bronchial mucous membrane or to pulmonary infarction or bronchopneumonia Of special interest are instances of left heart failure in which cough dominates the symptomatology and dyspnea is overlooked I have frequently observed such patients treated for bronchopulmonary disease It is important to recognize that a bronchitis in elderly persons is often an evidence of congestive heart failure Fever may be absent or only of slight degree Harrison Calhoun and Harrison[17] have emphasized the significance of cough not only as a symptom of left sided heart failure but as a factor in precipitating cardiac asthma intensifying dyspnea when present, and in increasing the strain on the right ventricle by elevating the pulmonary arterial pressure

Cough is an important symptom in certain forms of cardiovascular disease, even in the absence of heart failure It is observed in cases of luetic aneurysm with compression of trachea or bronchus, of mitral stenosis with very large left atrium or pulmonary artery compressing a bronchus or of a congenital double aortic arch forming a vascular compression ring around the trachea (p 781)

The cough is usually accompanied by mucopurulent expectoration In attacks of cardiac asthma and pulmonary edema the sputum is characteristically frothy and pink due to the presence of small amounts of blood In cases of mitral stenosis with pulmonary congestion the sputum is often rusty because of its content of hemosiderin bearing 'heart failure cells' When infarction of the lung occurs in left sided heart failure the sputum is often extremely tenacious and blackish red or it may be frankly bloody

Hemoptysis The expectoration of blood or bloody sputum in mitral stenosis and pulmonary edema has been mentioned In the presence of heart failure it is often due to an associated pulmonary embolism and infarction

Cyanosis Cyanosis of mild degree is often present in pure left sided heart failure but it is not a characteristic feature It is an early and frequent symptom of the pulmonary congestion due to mitral stenosis Cyanosis may be prominent in left ventricular failure when there is acute pulmonary edema or when there are complications such as bronchopneumonia pulmonary embolization or a coincident pulmonary emphysema

Pathogenesis of Cyanosis (see p 204)

Hoarseness Hoarseness is a rare symptom of left sided heart failure and has been attributed to paralysis of the left recurrent laryngeal nerve as a result of compression by a dilated pulmonary artery [45]

Physical Signs of Left Sided Heart Failure

The Heart *Enlargement of the Heart* may be revealed by inspection and palpation of the apical impulse by percussion and by roentgenologic and electrocardiographic examination

Gallop Rhythm (p 68) Gallop rhythm is usually heard only or best near the apex of the heart but it may be present to the left of the lower sternum or occasionally in other parts of the precordium Since gallop rhythm is audible as a rule, only in the presence of tachycardia, it may be brought out by having *the patient exercise The gallop is most distinct* in deep expiration and with the patient on his left side As a rule gallop rhythm does not occur or disappears with atrial fibrillation[12] but there are exceptions

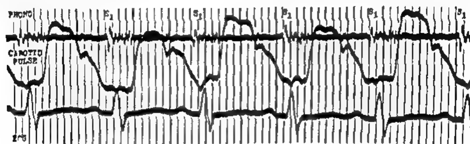
Pathogenesis of Gallop Rhythm (see p 69)

Accentuation of the Second Pulmonic Sound is due to the high tension in the pulmonary artery in left sided heart failure [10] The second pulmonic sound may become louder than the second aortic even when there is pronounced systemic hypertension

An Apical Systolic Murmur is frequently present due to a relative mitral insufficiency Tachycardia is frequent Tic tac sounds (embryocardia) may result from shortening of diastole by tachycardia with consequent even spacing of the two sounds *Atrial fibrillation* may be present

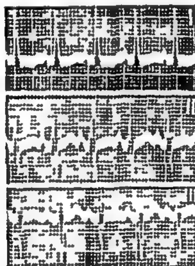
Cardiac Signs of the Underlying Disease These are discussed under the individual headings of hypertension, aortic stenosis, etc

Alternation of the Pulse may be a sign of left ventricular failure It is recognized by inflating *the cuff to the systolic pressure* As the cuff is very slowly deflated only alternate beats are heard for a distance of 2 to 10 or more mm Hg below the systolic level Rarely pulsus alternans is recognizable by palpation of the radial pulse unlike premature beats of pulsus bigeminus, the weak beat is very slightly closer to the succeeding beat than to the preceding one The heart sounds do not usually appear to be modified, but graphic records have demonstrated such alternation in intensity of the sounds[19] (Fig 53*A*) Alternation of the amplitude of contraction has been demonstrated by roentgen kymography[81] and electrokymography[21] Alternation of the QRS or T wave or of any other wave in the electrocardiogram may be associated with pulsus alternans This is termed electrical alternans (Fig 53*B*) It may be absent when the pulsus alternans is present or it may occur in the absence of pulsus alternans



Pathogenesis of Pulsus Alternans (see p 206)

The Lungs *Basal Râles and Emphysema* Sometimes the signs are those of a functional emphysema, as noted particularly by Weiss and Robb [102] Between attacks of cardiac asthma or pulmonary edema, there may be no râles or only a few crepitant or subcrepitant râles at the bases of the lungs posteriorly *The most common signs in moderately* advanced left heart failure are râles at the bases of the lungs posteriorly The râles are occasionally unilateral or predominantly on one side During or immediately after an attack of cardiac asthma there may be many sonorous or sibilant râles resembling the rhonchi of bronchial asthma With pulmonary edema, fine and coarse moist rales become more extensive and the entire chest may be filled with bubbling or gurgling sounds In addition there may be signs of a complicating bronchitis bronchiectasis bronchopneumonia or pulmonary infarction hydrothorax or other pleural effusion Pulmonary infarcts are almost always bland and disappear completely But occasionally they undergo suppuration [77]



Hydrothorax According to Bedford[8] hydrothorax occurred in 25 per cent of his 154 cases of left-sided heart failure A pleural effusion which often contains blood may follow pulmonary infarction Unlike the fluid of hydrothorax this effusion has the characteristics of an exudate Occasionally an encapsulated interlobar effusion is seen[2] or multiple localized pleural effusions may occur[72] usually on the right side [103] A localized effusion in the oblique or transverse fissure *may simulate the roentgen appearance of a* neoplasm or other pulmonary lesion, its disappearance with vigorous therapeutic measures has given rise to the expression "vanishing tumor" of the lung [101] Often the inter*lobar effusion persists for some time after* other manifestations of heart failure are well

controlled The interlobar localization of the effusion has been attributed to a previous obliterative pleurisy which spared the fissure but sealed it off from the rest of the pleural cavity Recurring pleural effusion has been reported in two cases of massive left atrial thrombosis Usually hydrothorax in the course of congestive heart failure appears predominantly or exclusively on the right

rough parallel and no causal relationship (p 192) The vital capacity is the sum of the reserve, tidal and complemental air (p 972) and its reduction is the result of changes in one or more of these primary lung volumes The *reserve air* is usually diminished, denoting a loss of pulmonary elasticity The *tidal air* is also diminished when heart failure is moderately severe The *complemental air* (inspiratory

side [57] but in Bedford's[3] cases of left sided heart failure the pleural effusion more often involved the left pleural cavity For further discussion see p 203

Lung Volumes

The *vital capacity* as well as the total pulmonary air space is greatly diminished in heart failure [78, 81, 102] The occurrence and severity of dyspnea has long been related to the reduction in vital capacity, but there is only a

capacity) is often markedly reduced indicating impaired distensibility of the lungs See also lung volumes in mitral stenosis (p 651) and in pulmonary emphysema (p 987)

In a study of 26 cardiac patients with low cardiac output, Richards et al [66] noted an increase in residual air and a reduction in complemental air even in compensated cases As definite congestive heart failure supervened complemental air was further reduced

and the reserve air was diminished. With extreme failure residual air was diminished and all lung volumes including vital capacity and total lung volume were decreased. They stressed the importance of increased heart size in producing these changes by encroaching on the thoracic space available for the lungs. On the other hand considerable evidence suggests that these alterations indicative of impaired elasticity and of impaired distensibility of the lungs in heart failure are due to rigidity caused by pulmonary vascular engorgement[7] or increased pulmonary capillary pressure.

Changes in lung volumes in heart failure

Roentgenologic Appearance of the Heart and Lungs in Left Sided Heart Failure[95a]

The *hilar shadow* is often increased both in density and width. Extremely wide (and pulsating) hilar shadows are also seen in cases of congenital heart disease such as interatrial septal defect, patent ductus arteriosus, in pulmonic valvular insufficiency, and occasionally in heart block.

The *lung fields* appear cloudy (Fig 54*A*) partly because of an accentuation and widening of the lung markings (i e the branches of the pulmonary vessels) and partly because of congestion, fibrosis or edema of the pulmonary tissue between the vessels.[69] The dense hilar

Fig 54 *A* Chronic venous congestion of the lungs in heart failure. Diffuse haziness of lung fields especially lower lobes. Prominent hilar vessels. Cardiac enlargement.
B Congestive heart failure with venous stasis in lower lobes and bilateral hydrothorax. Pulmonary infarct of right lower lobe may be obscured by pleural effusion.

depend on the nature of the underlying cardiac disease and the severity of heart failure and its pulmonary complication. Thus West, Bliss and colleagues[103] found no appreciable alterations in lung volumes in their patients with heart failure provided there was neither pulmonary edema nor hydrothorax.

The *increase in residual air* often present in congestive heart failure is similar to the finding in obstructive emphysema (p 987). Bronchial wheezes sometimes heard in heart failure especially during attacks of cardiac asthma also suggest the presence of bronchospasm in heart failure. As in obstructive emphysema there is a marked increase in uneven ventilation as measured by the elimination of pulmonary N_2 while breathing 99.6 per cent oxygen.[8]

shadows radiate in a fanlike fashion toward the periphery and particularly toward the base of the lungs. Where the engorged vessels run perpendicularly to the film they appear as conspicuous round shadows or nodular densities which may simulate miliary tuberculosis or carcinomatosis. Oblique views may disclose that these nodular densities are due to localized interlobar effusions.[70] There is often a diffuse haziness of the lung in its median and peripheral portions while the periphery is clear. Homogeneous mottled areas may result from alveolar exudation. Sometimes the homogeneous densities are indistinguishable from infarcts or consolidation. In pulmonary edema the shadows are usually widespread and symmetrical (Fig 55). Chronic pulmonary stasis with fibrosis and deposition of

hemosiderin produce nodular foci which may become calcified or rarely ossified (p 663)

Immediately after an attack of acute pulmonary edema there may be a cloudiness of the lung field in the area around the hilar shadows while the periphery of lung fields is clear [34] Then the shadow due to pulmonary edema extends to the bases The mechanism of this spread has been discussed by *Zdansky* [109] Free and encapsulated pleural effusions have been noted The roentgenologic picture of pulmonary engorgement may also be complicated by the coexistence of bronchopneumonia and pulmonary infarcts

The *cardiac silhouette* in left sided heart failure is determined chiefly by the underlying diseases for which the appropriate chapters should be consulted With the development of left sided heart failure there is evidence of progressive enlargement of the failing chambers With clearing of the heart failure the size of the heart is distinctly reduced

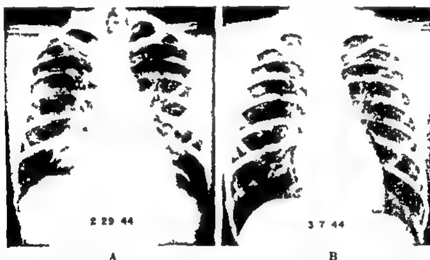

Fig 55 *A* Acute pulmonary edema in glomerulonephritis precipitated by intravenous infusions Exaggerated hilar and pulmonary markings Diffuse haziness especially of medial portions of lung fields with clearing at periphery and bases
B After recovery one week later

Circulatory Measurements

The *circulation time* is prolonged The arm to tongue time (p 213) exceeds 16 seconds the upper limit of normal and may be 40 seconds or more This is due to slowing of the blood stream in the dilated heart and in the congested lungs In the early stages of left sided failure the arm to lung time (ether) (p 215) may be normal indicating that the slowing is limited to the venous side of the pulmonary circulation and left cardiac chambers With frank left-sided failure both the arm to-lung and arm to-tongue time are prolonged

The *venous pressure* is normal in the absence of concomitant right sided heart failure

The *basal metabolic rate* may be slightly or greatly elevated (+15 to +60 per cent)[85] owing to excessive work of the muscles of respiration

The *arterial blood pressure* may be unchanged may fall or may become elevated (Hochdruckstauung[87 31]) depending in large measure on the underlying disease and the factors precipitating heart failure

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS OF LEFT SIDED HEART FAILURE

The diagnosis of left sided heart failure is made on the basis of the characteristic symptoms and signs of pulmonary congestion in a person with the types of cardiac disease which usually underlie left sided heart failure

The usual symptoms of pulmonary congestion are exertional dyspnea orthopnea paroxysmal dyspnea (cardiac asthma) pulmonary edema cough and hemoptysis The chief physical signs are râles at the bases of or throughout the lungs accentuation of the second pulmonic sound gallop rhythm and alternation of the pulse Many or all of these signs may be absent Roentgen ray examination reveals an enlarged heart prominence and widening of the hilar shadows and cloud

ing of the lung fields A prolonged circulation time is a valuable diagnostic confirmation

Differential diagnosis involves most often the distinction of left heart failure from bronchopulmonary disease as suggested by such symptoms as cough, dyspnea hemoptysis and asthma Roentgenograms of the chest physical and electrocardiographic examination to determine the presence of underlying cardiac disease and a careful history provide the needed data A prolonged circulation time distinguishes cardiac from bronchial asthma [72] Not infrequently a therapeutic test with the injection of one or more mercurial diuretics determines whether cough and/or dyspnea are due to cardiac failure or bronchopulmonary disease Dyspnea must be carefully evaluated to distinguish it from psychogenic disturbances in respiration

RIGHT-SIDED HEART FAILURE

Right-sided heart failure is most often combined with left sided heart failure In fact left sided heart failure with its associated pulmonary congestion and pulmonary hypertension, is the commonest cause of failure of the right ventricle Sometimes the entire heart fails simultaneously but the clinical features are predominantly those of right sided heart failure Occasionally, however, isolated right-sided heart failure is seen without left sided heart failure

CAUSES OF RIGHT SIDED HEART FAILURE

The underlying cardiac diseases which cause right-sided heart failure may be grouped as follows

1 Conditions associated with left sided heart failure and consequent pulmonary congestion and pulmonary hypertension which place a strain on the right ventricle Thus left-sided heart failure in essential hypertension, coronary artery disease and aortic and mitral valvular disease is followed usually in a few months or years by failure of the right ventricle

Under the heading of Bernheim's syndrome[8, 84] are included cases of pure right sided heart failure due to lesions such as hypertension or aortic stenosis which cause massive hypertrophy of the left ventricle including the interventricular septum The latter encroaches on the right ventricular chamber to such an extent that there is a functional obstruction to inflow into the right ventricle To satisfy the criteria for Bernheim's syndrome, left sided heart failure pulmonary disease or congenital cardiac lesions must be excluded as the possible cause of the right-sided heart failure The syndrome is not well established as an entity Selzer et al [83] have presented evidence based on hemodynamic studies with the aid of cardiac catheterization that cases of so called Bernheim s syndrome apparently represent instances of congestive heart failure in which dyspnea and other phenomena of left sided heart failure are inconspicuous, yet the catheterization findings are those of left-sided heart failure, pulmonary hypertension and right heart failure

2 Conditions which impair the function of the entire myocardium but which produce a predominant picture of right sided heart failure When the entire heart is affected, the right ventricle being weaker than the left fails more readily and the diminished output of the failing right ventricle spares the left ventricle e g rheumatic diphtheritic or toxic (Fiedler s) myocarditis severe anemias, beriberi and arteriovenous fistula

3 Primary diseases of the lungs, pulmonary vessels or pulmonic valve which cause strain and consequent failure of the right ventricle (cor pulmonale) (p 970) These instances of primary or isolated right ventricular failure are rare as compared with the cases of isolated left ventricular failure

4 Rare cases of predominant or isolated tricuspid stenosis cause failure of the right atrium and a clinical picture identical with that of right ventricular failure except for the signs of the primary disease

5 Conditions causing an obstruction to the inflow of blood into the right atrium such as constrictive pericarditis The resulting systemic venous engorgement produces a clinical picture like that with tricuspid stenosis in which there is a similar obstruction to inflow Prolonged ectopic tachycardias may also lead to right-sided heart failure

PATHOLOGIC PHYSIOLOGY OF RIGHT SIDED HEART FAILURE

This will be discussed in detail in Chapter 8 The symptoms of right sided heart failure are largely due to engorgement and elevation in pressure of the systemic veins and capillaries and the associated sodium water retention

PATHOLOGY OF RIGHT SIDED HEART FAILURE

Liver

The liver is dark red or brownish enlarged and firm because of chronic passive congestion[47] In cases of longstanding congestion it may undergo subsequent atrophy so that it is only slightly enlarged or even smaller than normal The term nutmeg liver refers to the appearance produced by the alternation of dark red and light brown areas The former is due to the central areas of venous congestion the latter to lesser congestion and the deposition of fat in the periphery of the lobule In the earliest phases of right sided heart failure with increased venous pressure there is dilatation of the central vein and sinusoids with narrowing of the liver cords Then there is centrolobular necrosis followed by capillary sclerosis and by organization and fibrosis of the central necrotic areas In addition poor nutrition may cause a fatty liver with diffuse fibrosis according to histologic studies of tissue obtained by needle biopsy[106] Eventually extensive fibrosis leads to *cyanotic induration* while necrosis and atrophy may cause *cyanotic atrophy* of the liver When the process of connective tissue formation and fibrous retraction is extensive the changes in the liver are described as cardiac cirrhosis[4] or cardiac fibrosis of the liver[64] Sclerosis of the hepatic veins[63] and of the superior vena cava[26] has been described, due presumably to the elevated pressure in these vessels during right sided heart failure The incidence of cardiac cirrhosis of the liver varies between 0 7 and 12 per cent of cases of heart failure depending on the criteria employed by different observers Cardiac cirrhosis is most likely to occur with multiple attacks of heart failure and especially when there is a very high hepatic venous pressure of prolonged duration I have observed it most often with functional or organic tricuspid stenosis and advanced right sided heart failure and with constrictive pericarditis The factor of an independent Laennec's cirrhosis is sometimes difficult to exclude Needle biopsy studies[106] may be helpful in making such diagnoses since clinical and laboratory data in heart failure are often inadequate to determine the character of associated hepatic disease But there is risk in needling the congested liver of heart failure

Peritoneal Cavity Gastrointestinal Tract Spleen and Pancreas

Increased capillary permeability and elevation of pressure in the peritoneal capillaries are the chief factors leading to the transudation of fluid and the appearance of variable and sometimes vast quantities of ascitic fluid in the peritoneal cavity Secondary infection of the ascitic fluid may cause inflammation and thickening of the peritoneum and of the peritoneal covering of the viscera especially the liver The hypertension of the portal circulation also causes passive congestion in the veins and capillaries of the entire gastrointestinal tract, with consequent edema thickening and occasionally hemorrhages

The *spleen* is enlarged dark red and firm (cyanotic induration), as a result of passive congestion and venocapillary hypertension of the portal (and hence of the splenic) circulation[43] According to Fowler[7] the spleen was sufficiently large to be theoretically palpable (i e over 300 gm) in 13 4 per cent of 97 cases of uncomplicated congestive heart failure and according to Wahi and Mathur[101] in 22 2 per cent The *pancreas* may also be the site of passive congestion

The Kidney

The kidney appears dark red and is firmer than usual because of chronic venous congestion The essential microscopic feature is the widening and engorgement of the intertubular veins and capillaries and usually also of the glomerular capillaries There is some proliferation of intertubular connective tissue but heart failure does not lead to significant fibrosis or contraction of the kidney

The Brain

Venous congestion with and without edema of the brain and leptomeninges, and alterations of the ganglion cells and nerve fibers have been described But the many cerebral symptoms seen in advanced heart failure are more probably due to severe cerebral arteriosclerosis sometimes with infarcts and encephalomalacia or to cerebral emboli arising in left atrial or ventricular thrombi

CLINICAL PICTURE OF RIGHT SIDED HEART FAILURE

Although the clinical pictures of right and left sided heart failure are sharply segregated for purposes of presentation and to emphasize their occurrence as isolated syndromes it

must be remembered that the symptoms of left and right sided heart failure are usually combined sooner or later, and often they appear almost simultaneously

Symptoms and Signs of Right Sided Heart Failure

The Heart and Lungs In the usual case of right-sided heart failure, the left heart is also insufficient and the signs in the heart and lungs are essentially those described under left-sided heart failure (p 146)

Cardiac enlargement is more pronounced and more universal than in pure left heart failure Roentgenograms may disclose definite enlargement of the right ventricle and atrium The shadows of the superior and inferior venae cavae become more distinctive The entire cardiac silhouette becomes enlarged to the left and right encroaching on both pulmonary fields and somewhat obliterating the individual cardiac contours There are insufficient comparative studies of the size of the heart but a few series indicate that the cardiac silhouette often undergoes distinct enlargement with failure and a diminution in size following recovery [74, 20] Comparisons are often difficult because of differences in technique and changes in the position of the diaphragm at the respective examinations during failure and in its absence

In cases of pure right sided heart failure secondary to intrinsic pulmonary disease, enlargement of the heart is often difficult to demonstrate There may be an enlargement only in the anteroposterior diameter or enlargement of the right chambers may be demonstrable in oblique views (p 105)

In combined right and left heart failure, râles at the pulmonary bases persist Hydrothorax occurs commonly especially on the right side or bilaterally Clouding of the medial and lower lung fields is frequently observed on roentgenologic examination Pulmonary infarction is common and may be associated with pleural effusion In cases of pure right sided heart failure due to pulmonary disease the roentgenologic findings in the lungs are those of the underlying pulmonary disease In cases of tricuspid stenosis and constrictive pericarditis with failure, the pulmonary fields are sometimes remarkably clear but hydrothorax is frequent

The *electrocardiogram* is not characteristic and is determined by the underlying disease or by complicating arrhythmias especially atrial fibrillation Prolongation of the QT interval is usual [16]

Subcutaneous Edema Edema, or the demonstrable accumulation of excessive fluid in the subcutaneous tissues, is a classic feature of right sided heart failure Usually it appears in a cardiac patient who has been suffering for months or years from dyspnea on exertion, orthopnea or cardiac asthma Occasionally a patient with heart disease who has never noted any of the above symptoms begins to complain of swelling of the feet or ankles which usually appears in the evening and subsides after a night's rest in bed A considerable amount of fluid may accumulate in the subcutaneous tissues before edema becomes apparent (invisible edema) This may be noted as an increase in body weight Conversely, the loss of invisible edema fluid may cause a reduction in weight and a continued diuresis after all visible edema has disappeared

The edema may occur in any part of the body, but because its localization is determined chiefly by an elevated hydrostatic capillary pressure, it is usually found in dependent parts of the body such as the feet, ankles (especially the inner malleoli), and pretibial region In a patient who has been in bed for some days or longer the edema is most prominent over the sacral region and may be overlooked unless this part of the body, which is now the most dependent, is carefully examined In patients with hemiplegia the edema is most conspicuous on the paralyzed side [78] Sometimes there is generalized, massive edema (anasarca) affecting all parts of the body including the genitalia, chest wall, arms and rarely, the face In the primary forms of right ventricular failure, in which orthopnea is usually absent and the patient sleeps in the recumbent position, there may be edema of the face or eyelids on arising But as a rule, edema of the face should suggest a renal etiology or some obstruction of the superior vena cava (Pathogenesis, see p 199)

Ascites Ascites or effusion of serous fluid into the abdominal cavity is the result of engorgement in the portal venous tributaries As a rule it is a later development and a less prominent feature than subcutaneous edema but in some forms of right sided heart failure (with tricuspid stenosis or constrictive pericarditis) there is considerable ascites with little edema There is also a group of cases of predominant right sided heart failure in

which ascites with little or with moderate peripheral edema follows shortly after an acute myocardial infarction The explanation for the early and outstanding ascites is uncertain It has been attributed to underlying cirrhosis of the liver or to infarction of the interventricular septum with consequent Bernheim's syndrome

The ascites may cause no subjective symptoms or the patient may notice only an increase in his abdominal girth Sometimes it leads to abdominal distention and distress or even to abdominal pain The ascites is often persistent and may recur repeatedly after aspiration In cases of constrictive pericarditis persistent and recurrent ascites is a characteristic feature (Pathogenesis see p 203)

Hydrothorax and Hydropericardium Subcutaneous edema and ascites are often associated with effusions into the pleural cavity (hydrothorax) (Fig 54*B*) and sometimes into the pericardial cavity (hydropericardium) to form the complete picture of cardiac dropsy Hydrothorax has been mentioned as occurring in left sided heart failure (p 146) as well as in right sided heart failure since the pleura drains into the pulmonary as well as into the systemic veins The pleural effusions in right-sided heart failure occur most often in the right pleural cavity or are most extensive on that side when there are bilateral effusions In left sided heart failure with regular rhythm the effusions according to Bedford and Lovibond[4] are usually on the left side but this has been questioned[47]

Pathogenesis of Hydrothorax (see p 203)

Usually pleural effusions are absorbed as heart failure improves but interlobar effusions are sometimes persistent (p 146) The chief effect of hydrothorax is to produce dyspnea or more often to exacerbate the dyspnea present by compressing the lung by diminishing its vital capacity and by reflex stimulation of breathing

Engorgement of Superficial Veins The large cervical veins and those on the dorsum of the hand may appear full and prominent In cases of advanced heart failure there may be pulsations of the superficial veins of the extremities[44] The retinal[49] and lingual veins[44] may also be conspicuously engorged with right sided heart failure

The normal pulsations of the cervical veins are best seen over the jugular bulb in the root of the neck with the patient supine In cases of right-sided heart failure the veins may become too distended to pulsate when the patient is supine As his head is gradually elevated a point of intense venous pulsation is reached Normally the cervical veins appear empty when a person is erect with severe right-sided heart failure these veins appear extremely engorged and their pulsations may be prominent The positive form of venous pulse (p 72) may be seen if there is associated atrial fibrillation or tricuspid insufficiency

Prominence of the superficial veins is an early sign of right-sided heart failure and may be noticeable before there is detectable subcutaneous edema, hepatic enlargement or other signs of heart failure This sign may persist even after rest in bed diuretics and other therapeutic measures have eliminated the edema Occasionally engorgement of the superficial cervical veins is revealed only by pressure over the right upper quadrant of the abdomen (hepato-jugular reflux) (infra) It is important to remember that in right-sided heart failure engorgement occurs in the tributaries of both the superior and inferior venae cavae When venous congestion is limited to the upper or lower portions of the body, some local venous obstruction should be sought

Enlargement and Tenderness of the Liver The enlarged liver can almost invariably be palpated clinically Its lower border may extend to the level of the umbilicus Hepatic enlargement is often present long before there is edema In infants and young children rapid enlargement of the liver is often the outstanding sign of cardiac failure while pulmonary signs and edema are often absent The liver often remains enlarged when all other symptoms of right sided heart failure have disappeared Often there is abdominal tenderness in the hepatic region due presumably to tension of the liver capsule With severe heart failure especially if there is significant tricuspid valvular insufficiency the liver pulsates synchronously with the right ventricular pulsations (see p 713)

The large liver may not only be tender on pressure but may cause spontaneous abdominal pain and this may be induced or intensified by exertion The abdominal pain rarely simulates that of cholelithiasis or cholecystitis Mild abdominal pain in patients with congestive heart failure may also be due to intense distention resulting from gastrointestinal disturbances (p 155) or ascites

Abdominal pressure over the engorged liver causes or increases visible engorgement of the cervical veins and a rise in venous pressure This phenomenon, known as the hepato jugular reflux is a diagnostic sign of right-sided heart failure and helps differentiate hepatic enlargement due to venous engorgement from that due to other conditions Hepatic or abdominal compression increases the venous return and intensifies the stasis in the cervical veins, owing to the inability of the failing right heart to handle the increased blood flow [24, 95]

Liver Function and Jaundice Hepatic congestion is often associated with a disturbance in the function of the liver [15] The latter is attributed to cellular hypoxia associated with an inadequate blood flow[68] and slowing of the blood stream as well as to cellular necrosis and atrophy secondary to venous congestion and hypertension Urobilinogen in the urine is increased [15] Hyperbilirubinemia is frequently present with right sided heart failure due to an increase in the direct and indirect (slow-reacting), bilirubin, especially the latter [89] Frank jaundice occurs in 2 to 5 per cent of the cases [46] The patients with jaundice usually suffer from combined left and right sided heart failure and have pulmonary infarcts as well as an engorged liver But jaundice may occur in the absence of infarction [76] In edematous areas the skin may not be jaundiced because the bile pigments do not enter into the edema fluid[88] or only to a slight extent,[1] possibly because of its low content of protein Jolliffe[43] found impairment of hepatic function indicated by excessive retention of injected bromsulfalein in 12 of 16 patients with right sided heart failure and similar findings have been reported by others [26, 95, 25] The van den Bergh reaction is positive There is some uncertainty whether the abnormal bromsulfalein test in cases of congestive heart failure actually denotes hepatic damage or is due entirely to circulatory stasis

The thymol turbidity test was abnormal in 31 per cent and the cephalin flocculation test in 22 per cent of the determinations made by Felder et al [6] in 135 cases of chronic protracted congestive heart failure They also noted an elevation of the alkaline phosphatase in 46 per cent of the determinations and in 83 per cent of the cases of cardiac cirrhosis studied at autopsy Although reported measurements of prothrombin time in congestive heart failure are not in universal agreement there appears to be a tendency to slight prolongation in prothrombin time and increased sensitivity to anticoagulants which act on the prothrombin [8] Deficient clearance of bromsulfalein has been attributed to slowing of the hepatic blood flow [67] but Sherlock[95] does not agree with this interpretation

Hepatic hypoglycemia has been said to occur much more often in congestive heart failure than is realized and has been held responsible for weakness, sweating, palpitation nervousness, irrational behavior and even convulsions or coma [59] Sudden but transitory improvement has been attributed to the intravenous administration of small doses of concentrated glucose solutions

Splenomegaly is found post mortem in 13 to 22 per cent of cases (p 151) but is only occasionally noted clinically Splenic enlargement was reported in 5 of 206 cases of congestive heart failure by Ibrahim et al [89]

Pathogenesis of Jaundice in Heart Failure (p 205)

Cyanosis A bluish discoloration of the skin and mucous membranes due to an excessive concentration of reduced hemoglobin in the blood is almost always seen in patients with right-sided heart failure It occurs most often and is most intense in the cases in which heart failure is secondary to pulmonary diseases or to congenital cardiac lesions causing a considerable admixture of arterial and venous blood When right sided heart failure complicates left sided heart failure dyspnea may be alleviated but cyanosis may appear or become intensified In left sided heart failure the severity of dyspnea is usually out of proportion to the cyanosis in right sided heart failure due to pulmonary lesions the cyanosis is often more prominent than the dyspnea

Pathogenesis of Cyanosis (p 204)

Fever usually denotes associated pulmonary infarction or bronchopneumonia or it may be due to rheumatic activity bacterial endocarditis or some other infection

Weakness may be a prominent symptom in advanced failure and is sometimes associated with extreme loss of weight and anemia (cardiac cachexia) It may be related to marked reduction in cardiac output to the increased work of respiration, to excessive diuresis or electrolyte disturbance, to nutritional deficiency, to associated cerebral, renal

or pulmonary disease to infection or to drug toxicity

Gastrointestinal Disturbances. Owing to venous engorgement anorexia and abdominal distention or a sense of fullness after meals are frequent Many gastrointestinal symptoms especially anorexia nausea and vomiting may occur not because of passive congestion but because of digitalis morphine or drugs The combination of meteorism with hepatic enlargement (and sometimes also ascites) may cause intense abdominal tension or even pain Constipation is sometimes distressing, more rarely there is diarrhea Intestinal bleeding is occasionally observed

Disturbances of the Nervous System Aphasia, paralyses convulsions and coma may be due to a complicating cerebral embolism with infarction and encephalomalacia The embolism arises from a thrombus in the left atrial appendage in cases of mitral stenosis or coronary heart disease and atrial fibrillation or on the wall of the left ventricle over the site of infarcation or aneurysm

There are numerous neurasthenic neurotic or psychotic manifestations which may or may not be directly related to the cardiac failure Scheinberg[70] measured the cerebral blood flow in congestive heart failure by the nitrous oxide method and found a reduction of 39 per cent associated with a marked rise in cerebrovascular resistance Similarly Moyer et al [65] noted a 20 per cent reduction in cerebral flow and increased cerebrovascular resistance However, Novack and associates[71] concluded that the reduction in cerebral blood flow was not due to the heart failure itself but to associated cerebral arteriosclerosis, since the cerebral blood flow in heart failure did not differ significantly from that in a control group of subjects chiefly between the ages of 50 and 70 presumably with cerebral arteriosclerosis without heart failure Similarly, a reduced cerebral oxygen consumption was attributed to older age and arteriosclerosis not heart failure These findings were interpreted to indicate that cerebral blood flow and cerebral metabolism (oxygen) tend to be maintained in heart failure despite a reduction in the cardiac output It is questionable therefore whether cerebral symptoms are due to heart failure itself except when the latter is very severe Headache is a common symptom Insomnia and bad dreams or nightmares are sometimes very distressing Hypochrondriasis and depression may be due to the patient's knowledge that he is suffering from heart disease or heart failure Occasionally there are true psychoses with disorientation, delirium hallucinations and delusions especially of a paranoid type [34] Psychotic symptoms as well as pronounced weakness may follow extreme diuresis after mercurial drugs Morphine and barbiturates are frequently contributory causes of mental symptoms Psychotic symptoms may be due also to digitalis intoxication or ammonium chloride acidosis to diarrhea to associated renal insufficiency pulmonary embolism bronchopneumonia or cerebral arteriosclerosis or to marked aberration in the blood electrolyte pattern In most cases of uncomplicated heart failure mental symptoms are absent

Renal Symptoms. *Nocturia* occurs frequently and may be due to an associated prostatic enlargement to the elimination of occult edema fluid when the patient is recumbent or to irritation of the bladder or urethra by concentrated urine Temporary anuria may follow active diuresis

Oliguria is a characteristic feature of right sided heart failure Since the diminution in urinary output parallels the severity of the heart failure, the urinary volume is usually a good index of progress When improvement occurs the volume increases with spontaneous or therapeutic diuresis a polyuria of 2 5 to 4 liters daily may appear

Urinary Findings

The *urine* is concentrated and has a *high specific gravity* usually between 1 025 and 1 030 However its sodium content is minimal [12, 80] When cardiac edema disappears as a result of spontaneous or therapeutic diuresis the specific gravity may be very low but the content of sodium and chlorides is increased The specific gravity of the urine may also remain low if cardiac failure complicates renal insufficiency or following frequent mercurial diuretics or prolonged and extreme restriction of sodium intake

Albuminuria is a common occurrence with congestive heart failure [84] Usually the albuminuria is slight, the concentration being less than 1 per cent and the daily excretion of albumin less than 1 gram Hyaline casts and sometimes granular and epithelial casts accompany the albuminuria Renal function as determined by urea clearance and PSP tests is usually depressed [11] (See also p 171)

The Erythrocyte Sedimentation Rate

It is widely believed that an increased sedimentation rate of erythrocytes falls to normal in the presence of congestive heart failure, notably in active rheumatic fever with heart failure[9] (p 835) But recent observations in 38 patients with congestive heart failure, before and after compensation was regained, disclosed that the majority of such patients exhibited elevated values, not only initially but after recovery as well[65]

Blood Chemistry

The *chemistry of the blood* may be altered Moderate *azotemia* (urea nitrogen between 20 and 40 mg per 100 cc blood) has been noted when there is severe oliguria Vigorous mercurial diuresis *may result in increasing azotemia despite a large urinary output*[30] Occasionally there is *hypoproteinemia*, the reduction being confined essentially to serum albumin Hypoproteinemia is most likely to occur after prolonged cardiac failure as a result of malnutrition, impaired hepatic formation of albumin, and perhaps also of a long continued loss of albumin in the urine and *in serous effusions The serum globulin* tends to be elevated[25] The arterial oxygen saturation is normal in many cases and almost always is above 90 per cent[83, 82] However a significant reduction in arterial oxygen tension accompanies even slight reductions in oxygen saturation in this range of the dissociation curve of oxyhemoglobin The venous oxygen in mixed venous blood in hepatic and in renal *venous blood is markedly reduced* and the respective arteriovenous oxygen differences are increased The arterial carbon dioxide content is normal or somewhat diminished as a result of hyperventilation The concentration of ammonia may be elevated and may account for cerebral symptoms[8]

Blood Electrolytes (See also pp 168 275)

The *concentration of sodium* in the plasma is usually diminished despite the reduction in urinary sodium[29, 61] It appears to be related chiefly to the low sodium intake of patients under treatment for congestive heart failure at the same time that they are receiving mercurial diuretics Indirect evidence suggests that the reduction in plasma sodium may be due in part also to the passage of significant amounts of this ion into the cells[29] On the other hand recovery from heart failure is associated with a restoration of plasma sodium to normal concentration

In general plasma chlorides behave like sodium Like the latter, chlorides are poorly excreted in the urine, but there is often a quantitative dissociation The concentration of chlorides may be diminished as a result of mercurial diuresis or as a result *of associated* pulmonary emphysema with carbon dioxide retention Under both circumstances bicarbonate concentration is increased, but in the former there is alkalosis, in the latter acidosis The concentration of chlorides may be increased and that of bicarbonate and hydrogen ions diminished (hyperchloremic acidosis) as a result of diuretics such as am*monium chloride or Diamox or resins,* while *the concentration of the sodium is normal* In advanced heart failure in the presence of marked renal impairment or as a result of extreme restriction of sodium intake both chloride and sodium concentrations may be greatly reduced

The *plasma potassium* is relatively normal but balance studies during recovery from *heart failure*[14] *and studies of potassium excre*tion following diuretics[8] suggest that this essentially intracellular ion may undergo significant shifts out of the cell Studies with radioactive K^{42} suggest that total body potassium is diminished in congestive heart failure even though the plasma (extracellular) potassium concentration is normal[14] The potassium concentration is usually somewhat reduced in cases with hypochloremic alkalosis caused by mercurial diuresis

Chiefly as a result of therapeutic measures but also because of complicating renal or pulmonary disease a variety of abnormal blood electrolyte patterns may be observed These are discussed in more detail in Chapter 11 *in connection with various therapeutic* measures

Circulatory Measurements (See Chap 10) The *circulation time is prolonged* (p 167)

The *blood volume* is augmented[22, 60] (p 166)

The *venous pressure* is elevated in contrast with the normal venous pressure of pure left *sided heart failure (p 165)*

The *cerebrospinal fluid pressure* is determined by the venous pressure and is elevated in cases of right sided heart failure

The *arterial blood pressure* undergoes no characteristic change

DIAGNOSIS OF RIGHT SIDED HEART FAILURE

The diagnosis of right-sided heart failure is usually simple in patients with known cardiac disease or with preceding left sided heart failure The combination of enlarged heart congested cervical and peripheral veins subcutaneous edema of the dependent parts, and hepatic enlargement usually suffices to make the diagnosis An elevation of venous pressure with or without pressure over the right upper quadrant of the abdomen is confirmatory In incipient right-sided heart failure the venous pressure may not be elevated However the tendency to systemic congestion may be demonstrated by the hepato-jugular reflux or by a rise in venous pressure following simple leg exercise Normally there is no rise in *venous pressure*

I have often seen middle-aged and usually obese women who complain of shortness of breath and swelling of the ankles because of which they were told their hearts were failing Study usually revealed that the dyspnea was due to lack of exercise and obesity or that it was merely a psychogenic inability "to take a full breath" or a tendency to sighing respiration The edema was usually hypostatic due to flat feet varicose veins obesity and prolonged standing That these individuals are not suffering from heart failure can be proven by the exclusion of underlying hypertension or heart disease, with roentgen ray examination of the chest and electrocardiography and by the finding of a normal venous pressure and normal circulation time

Differential diagnosis involves the differentiation between heart failure and the multiplicity of pulmonary renal hematologic hepatic and abdominal or thoracic diseases *which may produce dyspnea edema* venous engorgement cough hepatic enlargement, hydrothorax or pleural effusion or ascites In the presence of ascites with advanced heart failure it is necessary to differentiate tricuspid stenosis constrictive pericarditis and cirrhosis of the liver

If heart failure is present it should be possible to demonstrate some underlying causative cardiovascular disease Cardiac enlargement should be demonstrable except with constrictive pericarditis If the right heart has failed *the physician should demonstrate that* the venous engorgement and elevation of venous pressure concern both the superior and inferior caval systems and not merely one or the other A prolonged circulation time is diagnostic of heart failure in the absence of polycythemia vera On the other hand, fever severe anemia, hyperthyroidism beriberi severe emphysema and arteriovenous aneurysm tend to restore the prolonged circulation time of heart failure to within the normal range Sometimes the diagnosis of congestive heart failure is finally confirmed by a satisfactory response to digitalization low sodium intake and the exhibition of mercurial diuretics

FUNCTIONAL CLASSIFICATION OF HEART DISEASE (SEVERITY OF HEART FAILURE)

The New York Heart Association set up a classification of patients with congestive heart failure *which has proved useful in evaluating* their functional status and in prognosis In the latter connection the classification has been used in the study of the cardiac patient and pregnancy and of patients submitted to mitral commissurotomy The classification is based essentially on the patient's symptoms during various grades of activity Hence its value is limited by its dependence on the subjective reaction of the patient Self imposed or physician imposed inactivity and psychic factors as well as the cardiac status may influence this reaction

Class I Patients with cardiac disease but with *no limitation of physical activity* Ordinary physical activity causes no undue dyspnea, anginal pain fatigue or palpitation

Class II Patients with slight limitation of physical activity They are comfortable at rest and with mild exertion They experience symptoms only with the more strenuous grades of ordinary activity

Class III Patients with marked limitation of physical activity They are comfortable at rest, but experience symptoms even with the milder forms of ordinary activity

Class IV Patients with inability to carry on any physical activity without discomfort Symptoms of cardiac insufficiency or of the anginal syndrome may be present even at rest and are intensified by activity

COMPLICATIONS OF CONGESTIVE HEART FAILURE

The complications of congestive heart failure are those associated with the underlying cardiac disease those related to congestion or elevated venocapillary pressure in various

tissues or organs and those due to therapeutic measures and to intercurrent disease

Venous thrombosis in the lower extremities and subsequent pulmonary embolism are among the most frequent and most serious complications of congestive heart failure Pulmonary embolism may be associated with infarction and distinct clinical symptoms such as chest pain cough hemoptysis and fever But often there are only non localizing manifestations such as fever weakness, transient dyspnea or cyanosis or tachycardia restless ness and anxiety and these are overshadowed by the manifestations of heart failure itself Commonly the heart failure is intensified or is refractory to treatment because of recurrent pulmonary embolism

Pulmonary emboli may also arise from thrombi in the right atrium especially in patients with atrial fibrillation and heart failure In idiopathic forms of heart failure pulmonary emboli arise from mural thrombi in the right ventricle (p 624)

Arterial emboli may occur as a result of mural left ventricular thrombi in cases of coronary heart disease or from the left atrium in cases of heart failure with atrial fibrillation

Rarely venous thrombosis in the upper extremities occurs as a complication of cardiac failure Loring[5] collected 83 cases from the literature and added four additional cases Furthermore such venous thrombosis may be complicated by pulmonary emboli and infarction, as in the six cases reported by Tomlin ■

The variety of other pulmonary complications besides embolism and infarction have been mentioned notably bronchopneumonia, pleural effusion and pulmonary edema

Other complications include cerebral vascular insufficiency cerebral thrombosis or embolism renal insufficiency cardiac cirrhosis colitis, bacterial endocarditis digitalis toxicity and disturbances in plasma electrolyte pattern

COURSE AND PROGNOSIS OF CONGESTIVE HEART FAILURE

The course and cause of death in congestive heart failure are often determined or modified by the underlying cardiac disease Death is often precipitated by a pulmonary or cerebral embolism and infarction or by an acute coronary occlusion Acute pulmonary edema is a frequent form of termination In their analysis of the causes of death in 185 patients with congestive heart failure, Williams and Rainey[107] emphasized the relative increase in importance of fatal pneumonias Since their study the liberal use of sulfonamides and antibiotics has sharply reduced the incidence of fatal pneumonia Uremia is fairly common as a cause of death in patients with malignant hypertension or nephritis and heart failure

Left sided heart failure ■ often variable in its course and duration I have known cardiac patients who have suffered from exertional dyspnea and slight orthopnea for ten or more years before the symptoms of right sided heart failure developed In patients with mitral stenosis mild symptoms of pulmonary congestion are almost part of the disease itself, for they occur early and may last many years before the patient is unable to carry on his normal activities However in the presence of dyspnea on slight exertion or at rest, repeated attacks of cardiac asthma recurrent pulmonary edema alternation of the pulse or persistent gallop rhythm, the outlook is usually unfavorable

Most of the studies on prognosis in heart failure state that the duration of life in cardiac disease complicated by right heart failure is only one to two years and rarely up to five Grant[35] found the average duration of life in the presence of venous congestion was two and ■ half years Williams and Rainey[107] found that in the period between 1931 and 1935 patients hospitalized with congestive heart failure due to rheumatic heart disease lived 32 months, those with arteriosclerotic heart disease 40 months and those with luetic heart disease 11 months But in recent years I have seen many patients who have survived five to ten years or more after the development of right-sided heart failure This is undoubtedly due to judicious restriction of sodium and administration of mercurial diuretics in the past twenty years

In general the outlook is relatively favorable if the symptoms of congestive failure subside rapidly and completely with appropriate treatment The less intense and prolonged the required treatment before recovery ■ effected, the more probable is the persistence of recovery

An important clue as to the patient's course ■ obtained from a study of his renal excretion of sodium and his response to the in

gestion of moderate amounts of sodium chloride[39] Some patients excrete sodium fairly well after disappearance of their symptoms of heart failure and there is no recurrence of symptoms or evidence of water retention following the daily ingestion of 5 to 10 gm of sodium chloride for five days As a rule heart failure in these patients was induced by an infection a pulmonary infarct anemia or some other factor which subsided or was eliminated by treatment These patients have a relatively good immediate prognosis and their hearts remain compensated with little or no sodium restriction and without the use of mercurial diuretics

At the other extreme is a host of patients who even after vigorous treatment and control of overt symptoms excrete almost no sodium in the urine and promptly experience a retention of fluid and recurrence of symptoms following the ingestion of as little as 1 to 2 gm of sodium chloride daily Heart failure in these patients can only be controlled by extreme sodium restriction and the frequent administration of mercurial diuretics in addition to other therapeutic measures Other patients fall between these two extremes their outlook for maintenance of clinical improvement may be graded according to their renal excretion of sodium and their response to the ingestion of sodium chloride

The outlook is relatively better if there is an obvious precipitating factor which can be eliminated than if congestive heart failure appears without any apparent immediate cause or as a result of one which cannot be treated Sodeman and Burch[37] found that of 47 patients in whom congestive heart failure appeared gradually and without apparent precipitating cause 16 were unable in spite of treatment to compensate sufficiently to carry on minimal normal activity On the other hand in 54 patients with a demonstrable precipitating cause for congestive heart failure compensation was established rapidly under treatment so that the patient could resume his activities

The outlook is also relatively better in the well to-do than in persons of low economic level Cooperation and intelligent execution of the physician s orders by the patient and his family also improve the outlook The prognosis in any given case of congestive heart failure should be guarded even when it appears relatively favorable because of the danger of serious complications or sudden death

Chapter 8

THE PATHOGENESIS OF CHRONIC CONGESTIVE HEART FAILURE

Chronic congestive heart [illegible] pro longed impairment of th[illegible] the heart to maintain an adequa[illegible] to the tissues. The manner in [illegible] ability arises was discussed in [illegible] on the etiology of heart failure. [illegible] concerned here with the mechanism [illegible] which such cardiac impairment lea[illegible] manifesta tions of congestive heart [illegible]

PATHOLOGIC PHYSIOLOGY OF HEART FAILURE

The disturbances in physiology of the circulation are characterized by: (1) Alterations in circulatory dynamics, particularly in blood flow and in pressure relationships throughout the cardiovascular system. (2) Abnormalities in fluids and electrolytes, particularly in the quantity and distribution of body water and in the total body content and concentrations of sodium.

ALTERATIONS IN CIRCULATORY DYNAMICS

The Cardiac Output in Congestive Heart Failure

Since the function of the heart is to provide an output of blood which is adequate for bodily needs throughout the range of physiologic activity, heart failure may be defined to indicate that the output is no longer adequate. But there is no direct method of determining body needs or the adequacy of the blood flow for these needs. Demonstration of a deficiency of cardiac output relative to body needs depends on the presence either of certain clinical symptoms or of disturbances in circulatory hemodynamics. The determination of cardiac output even under basal conditions presents technical difficulties (p 209). These are increased when cardiac output is determined during exercise. Furthermore we do not have satisfactory normal standards to indicate what the cardiac output should be for the variety of stresses to which the body is ordinarily subjected in the course of its physiologic activities.

Available determinations of cardiac output in congestive heart failure represent chiefly cardiac outputs with the subject at rest. Most investigators have noted at least a small diminution in cardiac output in the majority of cases of congestive heart failure. Earlier determinations of the cardiac output by the dye method[41], by the acetylene method[46, 47, 11, 114] and by physical methods[133] all showed that the cardiac output was usually reduced in groups of cases of severe heart failure, but there was often no significant reduction in cardiac output in patients with mild heart failure, and there was some overlapping of the values of cardiac output in patients with congestive heart failure and those with compensated heart disease as well as in normal persons. The accuracy of some of the methods used has been questioned, and indeed recent use of the more accurate direct Fick method (p 209) has disclosed more distinct reductions in cardiac output in heart failure than those determined previously[98, 74, 100, 141] but even among the more recent observations there are normal cardiac outputs in some patients with mild grades of heart failure.

It is difficult to define mild heart failure when applying the term to a given patient. Usage has not clarified the distinction between the expressions diminished cardiac reserve and heart failure, nor have we evolved satisfactory criteria for sharply defining the stage at which diminishing reserve is actually heart failure. The patient with rheumatic cardiovalvular disease who is generally regarded as well compensated, i.e. not in failure, can usually be shown to have a diminished cardiac reserve as compared with

his normal fellow, when he is subjected to severe or prolonged forms of physical exertion. The factors of physical fitness or training vary in different individuals and exaggerate the problem of defining mild heart failure on the basis of physiological tests or the development of symptoms such as breathlessness. Nevertheless, the response of the cardiac output to a standardized exercise test has been studied in patients with heart failure as well as in normal subjects.[69] These observations have shown that the cardiac output following exercise does not increase to a normal degree in patients with congestive heart failure. In mild cases of failure the cardiac output may be normal at rest and rise less than normally and presumably inadequately with exercise. This denotes some, although diminished, cardiac reserve. In very severe cases of heart failure the cardiac output is low and presumably inadequate even when the patient is at rest; with exercise there may be no increase whatever in the cardiac output, indicating no cardiac reserve—i.e., the cardiac output at rest [redacted] the maximal which the heart can deliver. But occasional cardiac patients with clinical evidence of heart failure may have a normal cardiac output at rest and an apparently normal increase with exercise even when they exhibit abnormal breathlessness during and after the exercise.[33] In such cases, however, the rise in cardiac output causes an abnormal rise in pulmonary capillary and arterial pressure.

In summary, the determinations of cardiac output in congestiv[redacted] heart failure generally confirm an association between the presence of heart failure and a diminished cardiac output. With some exceptions the correlation [redacted] quantitative in that the cardiac output is more regularly and more intensely diminished with more advanced heart failure. Furthermore, the ability of the heart to increase its output with exercise is depleted with increasing severity of the heart failure. However, in the light of the definition of heart failure in terms of inadequate cardiac output, one might anticipate a more consistent and a more marked reduction in cardiac output than one occasionally observes, particularly in the early and milder cases of heart failure. This deficiency in correlation may be due partly to technical difficulties in the determination of the cardiac output and partly to compensating homeostatic mechanisms that tend to maintain or restore the cardiac output as close to normal as possible.

Relation between Changes in Cardiac Output and Improvement of Symptoms. If heart failure is related to a deficiency in cardiac output, clinical improvement should correspond to an augmentation of the cardiac output. Harrison et al.[44] determined the cardiac output in 15 patients with congestive heart failure and again after the symptoms of heart failure had disappeared. With clinical improvement the cardiac output per minute increased in 3 cases and diminished in 7 cases, and the stroke output increased in 9, diminished in 3; there was no change in the remaining cases. On the other hand, Seymour et al.[103] found that the mean cardiac output during heart failure was 31 per cent less than after improvement; the output per minute and per stroke increased in every case when heart failure was controlled. More variable but consistent increases in cardiac output were reported by Eichna et al.,[29] McMichael and Sharpey Schafer[88] and Howarth and associates,[74] using the direct Fick method, observed striking increases in cardiac output in patients with low cardiac output and congestive heart failure when the patients were treated by digitalis, venesection and the application of tourniquets.

Reduced Cardiac Output without Symptoms of Congestive Heart Failure. Although the cardiac output is generally reduced in patients with congestive heart failure, it does not follow that the symptoms which characterize congestive heart failure are directly and specifically due to the deficient cardiac output, i.e., to an inadequate blood flow to individual tissues or organs. Thus in various states of shock or collapse due to trauma, hemorrhage or other causes the cardiac output is usually much lower than in cases of congestive heart failure, yet dyspnea, orthopnea, cardiac asthma, subcutaneous edema and other cardinal features of congestive heart failure are absent or insignificant. Conversely, the symptoms in shock which can be clearly related to a reduction in cardiac output, i.e., to an inadequacy of blood supply, such as weakness, mental torpor, fatigability, hypothermia, hypotension, are not observed or are overshadowed in cases of congestive heart failure.

Cardiac Failure with High Cardiac Output. There are groups of cases with unequivocal features of congestive heart failure in which

the cardiac output is actually increased This paradox is readily explained if one bears in mind that the physiologic definition of heart failure relates cardiac output to the needs of the tissues and not to some absolute normal Severe anemia, hyperthyroidism arteriovenous fistula beriberi advanced pulmonary emphysema with arterial hypoxemia pregnancy and occasionally advanced osteitis deformans are conditions which are or may be associated with an augmented cardiac output These abnormally high outputs are presumably necessary to supply increased tissue demands or to compensate for some factor interfering with an adequate supply of oxygen (p 186)

When cardiac failure develops as a complication of these conditions the cardiac output falls somewhat from the previously elevated levels but these reduced cardiac outputs are still distinctly above normal It is presumed however that these cardiac outputs although elevated are insufficient for body needs and therefore lead to the manifestations of heart failure If the heart failure is controlled e g by digitalis but the basic condition such as severe pulmonary emphysema remains the cardiac output is increased [illegible] If the basic condition responsible for the primary increase in cardiac output is controlled or cured the cardiac output falls to normal In a case of beriberi heart failure studied by Burwell and Dexter[5] the cardiac output was 11 8 liters and fell to a normal of 5 3 liters after clinical recovery

Cardiac Output Arterial Blood Pressure and Peripheral Resistance The systemic arterial blood pressure is not significantly altered during congestive heart failure except as it may be affected by the underlying cardiac disease or other factors Occasionally the blood pressure has been noted to be higher during severe heart failure (stauungshochdruck—Traube) than after recovery Since the peripheral systemic resistance (R) is proportional to the blood pressure (B P) and inversely proportional to the cardiac output (C O)

$$R = k\frac{B\ P}{C\ O}$$

An unchanged blood pressure with a diminished cardiac output indicates that the systemic resistance is increased in congestive heart failure (chiefly due to arteriolar vasoconstriction)

In cases of high-output heart failure the peripheral resistance is diminished not as a result of the heart failure but as a primary abnormality in the underlying disease e g hyperthyroidism or arteriovenous fistula The mean blood pressure may be normal slightly increased or slightly diminished, but the resistance is diminished to a greater degree hence the cardiac output is increased With the development of heart failure there may be a slight increase in the peripheral resistance which however, is still much below normal Therefore the cardiac output may fall somewhat, but is still more than normal

The blood pressure and peripheral resistance in the pulmonary circulation undergo changes which are often different and due to different mechanisms from those in the systemic circulation In left sided heart failure the pulmonary artery pressure and resistance are both usually increased at rest [illegible] but occasionally the pulmonary blood pressure is normal at rest[illegible] while the resistance is increased The increased resistance is located in the pulmonary capillaries and veins whereas the resistance in the pulmonary "arterioles" may or may not be increased in isolated left heart failure Exercise raises the pulmonary arterial blood pressure in heart failure, whether it is normal or elevated at rest [illegible] The pulmonary blood pressure rises with exercise but the cardiac output may or may not be augmented On the other hand the systemic blood pressure does not rise with exercise despite an increased cardiac output indicating that the systemic peripheral resistance diminishes with exercise in such cases

In right sided heart failure there is increased pulmonary blood pressure and increased pulmonary vascular resistance at rest Both increase further with exercise When the right heart failure is due to primary pulmonary disease the increased resistance is localized in the pulmonary arterioles When it is secondary to left sided heart failure the increased resistance is in the capillaries and veins as well as in the arterioles

Oxygen Utilization and Cardiac Output The provision of oxygen to the tissues after the blood becomes oxygenated is determined by the blood flow (cardiac output) and the amount of oxygen extracted per unit of blood (arteriovenous oxygen difference) Thus O_2 (Oxygen consumption) = C O (cardiac output) × (A_{O_2} − V_O) (arteriovenous oxygen difference) Normally an adult with a body

surface area of 1 6 sq meter may have a cardiac output of 5 liters per minute and an arteriovenous oxygen difference of 4 cc per 100 cc of blood (or 40 cc per liter) Such an individual consumes about 200 cc of oxygen per minute at rest (basal metabolism)

$$O_2 = \frac{5 \text{ liters}}{\text{min}} \times \frac{40 \text{ cc}}{\text{liter}} = \frac{200 \text{ cc}}{\text{min}}$$

During exercise oxygen needs increase and oxygen consumption can be readily increased 100 per cent or more In the normal individual this additional supply is provided chiefly by an increase in cardiac output, and to a lesser extent by increased extraction of oxygen from each unit of blood Thus for a required oxygen consumption during exercise of 400 cc instead of 200 cc per minute the cardiac output may be increased to 8 liters and the oxygen extraction per liter of blood (arteriovenous oxygen difference) to 50 cc per liter

$$O_2 \text{ (cc /min)} = \frac{8 \text{ l}}{\text{min}} \times \frac{50 \text{ cc}}{\text{l}} = \frac{400 \text{ cc}}{\text{min}}$$

In congestive heart failure the oxygen consumption at rest (basal metabolism) is somewhat increased possibly owing to increased work of the muscles of respiration Thus instead of an oxygen consumption of 200 cc per minute as in the above theoretical example, it might be 240 cc Since the cardiac output is *diminished in heart failure, the needed oxygen* supply is obtained by an abnormally large oxygen extraction per unit of blood Thus if the cardiac output is 3 liters instead of the normal 4 liters in the above example the arteriovenous oxygen difference (extraction) is 80 cc per liter instead of 40 cc

$$O_2 = \frac{3 \text{ l}}{\text{min}} \times \frac{80 \text{ cc}}{\text{l}} = \frac{240 \text{ cc}}{\text{min}}$$

Since the arterial oxygen is usually normal in heart failure (190 cc per liter) the mixed venous oxygen would be only 110 cc per liter During exercise the patient with heart failure can increase his output less than normally or not at all Similarly he may not be able to increase his oxygen consumption and an increased oxygen debt is sustained When oxygen consumption is increased during exercise in a patient with congestive heart failure, most or all of the increase is effected by greater oxygen *extraction per unit of blood* rather than by increased blood flow (cardiac output)

Increased oxygen consumption is an index of increased bodily requirement When cardiac function is normal, an augmented cardiac output supplies most and increased oxygen extraction some, of the increased oxygen need When the heart fails the cardiac output no longer contributes its share to increased bodily requirement for oxygen and the elevated oxygen consumption must be supplied in increasing degree by greater oxygen extraction When heart failure is mild oxygen extraction per unit of blood may be normal at rest and increased abnormally with exercise In severe heart failure, oxygen extraction is excessive at rest and more so with exercise In very severe heart failure maximal oxygen supply is effected at rest for a given low cardiac output by maximal oxygen extraction Neither oxygen consumption cardiac output nor oxygen extraction can be increased with exercise

It is apparent that increasing severity of congestive heart failure is indicated by progressively increased oxygen extraction Since arterial oxygen usually remains relatively normal, there is a progressive diminution in *mixed venous oxygen as the cardiac output* fails to supply oxygen requirements

In diseases with high cardiac output such as arteriovenous fistula, severe anemia, etc (but not hyperthyroidism) the oxygen consumption is normal despite the augmented blood flow Thus the oxygen extraction per unit blood is low i e 25 cc per liter instead of 40 to 50 cc, and the mixed venous oxygen is 165 cc instead of 150 to 140 cc For example if the oxygen consumption (O_2) is normal at about 200 cc per minute and the cardiac output elevated to 8 liters per minute, the oxygen extraction (arterial oxygen (190 *cc per liter) — venous oxygen (165 cc per* liter)) would be 25 cc per liter

$$O_2 = \frac{8 \text{ liters}}{\text{minute}} \times \frac{25 \text{ cc}}{\text{liter}} = \frac{200 \text{ cc}}{\text{minute}}$$

When the heart fails, the cardiac output falls somewhat from this high level and the oxygen consumption (which remains normal or elevated at rest) is effected by an increased oxygen extraction However just as the cardiac output, though diminished, may remain above normal levels the oxygen extraction though increased as in low output failure may remain below normal levels

In the above example the high cardiac output may fall in heart failure from 8 liters to 6 5 liters the oxygen consumption may remain 200 cc per minute, and the oxygen extraction would rise to 31 cc instead of 25 cc

but would still be less than the normal of 10 to 50 cc per liter

$$O_2 = \frac{6.5 \text{ liters}}{\text{minute}} \times \frac{31 \text{ cc}}{\text{liter}} = \frac{200 \text{ cc}}{\text{minute}}$$

Pulmonary Ventilation and Oxygen Consumption in Heart Failure

Pulmonary ventilation in heart failure is discussed on page 147 It is mentioned here to call attention to the limitations which congested lungs in heart failure may impose in supplying oxygen to the blood and thence to the tissues As a rule the blood is adequately oxygenated at the expense of increased ventilation per unit of time accomplished by increased respiratory effort and work of the respiratory muscles

The Intracardiac Pressures

When the work of the right ventricle is increased by a pathologic lesion such as pulmonic stenosis the cardiac output may be maintained at normal levels by compensatory hypertrophy The right ventricular systolic pressure is elevated to various heights above 30 mm Hg the upper limit of normal and may even equal or exceed left ventricular pressure On the other hand the end diastolic pressure remains normal at 5 mm Hg or less as long as compensation is complete With the development of heart failure the ventricular end diastolic pressure rises to 10 to 20 mm Hg or higher The right atrial pressure also rises its pressure being approximately equal to the elevated end diastolic pressure of the ventricle[17, 66] Similar elevations of the right ventricular end diastolic pressure and right atrial pressure occur in right ventricular failure due to a variety of other causes including preceding left heart failure

Similarly when the left ventricle fails the left ventricular end diastolic pressure rises[162] and subsequently the left atrial pressure rises to the same degree When failure of the left side of the heart is due to mitral stenosis left ventricular end diastolic pressure is normal but the pressure in the left atrium the failing chamber is quite elevated

Venous Pressure The elevated right atrial pressure in right-sided heart failure is reflected in a corresponding rise in pressure in the venae cavae the smaller systemic veins and presumably in the systemic capillaries The venous pressure in the antecubital vein normally between 4 and 10 cm water (3 to 8 mm Hg) usually measures 10 to 20 cm but occasionally is as high as 30 cm water or more In milder cases of right heart failure the systemic venous pressure may be normal at rest but elevated with exercise

In isolated failure of the left side of the heart the systemic venous pressure is normal However, the elevated left atrial pressure is reflected in a corresponding increase in pressure in the pulmonary veins and pulmonary capillaries

The rise in venous pressure denotes an inability of the failing chamber to accept and eject the venous return as competently as the normal chamber The venous pressure is thus the resultant of these two factors venous return and cardiac accommodation to changes in venous return This may also be expressed in terms of the formula Pressure = blood flow (venous return) × resistance In heart failure the blood flow or venous return is usually diminished for the venous return equals the cardiac output Since the venous pressure is elevated whereas the blood flow is diminished the resistance must be increased to a greater extent than the blood flow is diminished The increased resistance is apparently due to the resistance offered by the failing chamber with its high residual volume and high end diastolic pressure

Factors which increase the venous return such as shifting from the upright to the recumbent position exercise infusions and transfusions do not raise the venous pressure in the normal individual since the increased venous return is readily accepted by the heart and translated into an increased cardiac output In heart failure an increased venous return cannot be properly accepted and ejected by the failing chamber This leads to further stasis and increased pressure in the failing chamber and in the veins proximal to it[69, 134] On the other hand changing from the recumbent to the upright position venesection[74] and mercurial diuresis[10] which tend to reduce the venous return depress the elevated venous pressure in heart failure

It is claimed that heart failure is associated with increased venomotor tone (diminished venous distensibility)[161] just as there is increased vasomotor tone of the arterioles The increased venous pressure in heart failure has been attributed to this heightened venous tone[22] However, increased venous tone per se could not account for such pressure change Thus in cases of shock due to hemorrhage

there is marked increase in venous tone but a fall in venous pressure The fall is due to a decrease in venous return without an increase in cardiac resistance to inflow On the other hand the venous pressure may be normal in mild right sided heart failure despite increased venomotor tone Nevertheless simple *leg exercise raises the venous pressure not* because of a rise in venous tone but because the increased venous return due to exercise cannot be handled by the failing right heart

The Circulating Blood Volume

That the circulating blood volume is increased in congestive heart failure has long been indicated clinically by the presence of intense venous engorgement (high venous pressure distention of superficial veins hepatic enlargement and pulmonary engorgement) without a corresponding depletion of the arterial system The absence of substantial arterial depletion is indicated by the maintenance of arterial blood pressure and absence of cold extremities or other phenomena of shock An increase of circulating blood volume in cases of congestive heart failure is also indicated by the observation at necropsy of dilated blood filled cardiac chambers and by the intense engorgement of the blood vessels and viscera including the lungs liver and gastrointestinal tract According to Nylin[112] *most of the increased blood volume is* in the cardiac chambers (See also Heimbecker et al [67])

Actual determinations of the circulating blood volume while in some disagreement mostly reveal a definite increase in patients with congestive heart failure (infra) Hamilton *and his co-workers*[61] *demonstrated* an augmentation of the intrathoracic blood volume the volume of blood in both the heart and in the lungs being increased during congestive heart failure but not in patients with compensated heart disease Gibson and Evans[56] found the total blood volume definitely increased during congestive heart failure but especially in patients whose venous pressure exceeded 10 cm of water and whose circulation time was prolonged When the venous pressure was above 15 cm of water the average increase in the circulating blood volume was roughly parallel to the prolongation in circulation time and the elevation of the venous pressure With the subsidence of symptoms the blood volume fell the diminution being greatest in those patients with the greatest clinical improvement In most patients the blood volume decreased a liter or more and occasionally there was a reduction of 3 5 liters

Wollheim[160] also found in extensive studies of the circulating blood volume that this was increased in most patients with cardiac failure A study of his cases reveals that the patients with an increased blood volume were suffering from congestive heart failure termed by Wollheim[160] plus decompensation Of the patients with a diminished blood volume (40 to 60 cc per kilogram) the so called group of minus decompensation, many included instances of shock with or without congestive heart failure Insufficient clinical data are provided in Wollheim's publication to permit an interpretation of his cases and findings

While studies using the dye dilution method and some of those using radioactive iron have fairly uniformly disclosed an increase in plasma volume in heart failure,[66 6 133 99] some of the recent measurements of red cell volume by tagging erythrocytes with P^{32},[1 118 126] indicated that there is little or inconstant increase in red cell volume or in plasma or total blood volume in most patients with congestive heart failure These are in some disagreement with the determinations of Nylin [112] who used erythrocytes tagged *with* P^{32} *or thorium B and found uniform in*creases in red blood cell volumes which became more prominent with increased severity and especially with increased duration of the congestive heart failure More recently Reilly and associates using radiochromium Cr^{51} found an increased blood volume in the majority of patients with right heart failure but not in those with left ventricular failure or in mitral stenosis alone [1] findings similar to those of Nylin and Hedlund [113] Brown et al found that the whole blood volume and *the volume of red blood cells determined by* carbon monoxide and radiochromium Cr^{51} usually increased in congestive heart failure and decreased with improvement and similar findings were reported by Gunton and Paul who used P^{32} tagged erythrocytes Eisenberg [40] using the radio-chromium method found an increase of 20 per cent in blood volume (23% in cell mass, 17% in plasma volume) in congestive heart failure In mild case there was a 14 per cent increase in severe cases a 38 per cent increase in blood volume Increased blood volume was correlated with

the degree of cardiac enlargement, following treatment reduction in blood volume occurred and paralleled diminution in cardiac size

The reason for the discrepancy between blood volumes in heart failure determined by the dye method and those determined by tagging red blood cells may be clarified by a consideration of the total body hematocrit relative to that determined from venous blood as is usually done The hematocrit determined from blood drawn from a large vein is higher than the over all body hematocrit (red cell volume relative to total blood volume)[35, 8, 73] Thus plasma volumes and total blood volumes determined from red cell volumes and venous hematocrit are both underestimated Recently Schreiber and associates[1, 9] made simultaneous determinations of the red cell volume with P^{32} and of the plasma volume by means of I^{131} labeled human serum albumin in control subjects and in patients with congestive heart failure They found that the mean values for red blood cell volumes and plasma volumes in heart failure were elevated above those in control subjects and fell with compensation Furthermore during heart failure the hematocrit determined from venous blood relative to the total body hematocrit was even greater than normal thus tending to further underestimate plasma volume and total blood volume as calculated from red cell volume and venous hematocrit This may account for some of the relatively slight increases in blood volume or normal blood volumes reported in congestive heart failure, when the blood volume was determined from the red cell volume and hematocrit

The increase in plasma and total blood volume in heart failure is relatively small in comparison with the vast increase in extracellular fluid (plasma plus interstitial fluid) observed in patients with heart failure especially those with severe edema and effusions in the serous cavities Plasma volume is often increased 10 to 20 per cent in moderately severe cases of heart failure 30 to 50 per cent in very severe cases On the other hand the extracellular fluid chiefly interstitial fluid may be increased 100 per cent or more

The Circulation Time (p 213)

As a rule the circulation time (arm vein to tongue) in cases of congestive heart failure varies between 20 and 40 seconds instead of the normal of 10 to 16 seconds but occasionally it is 50 seconds or more Most of the circulatory slowing occurs in the pulmonary vessels and/or in the enlarged cardiac chambers[35, 108, 18, 112] The circulation time (arm to-tongue) may be prolonged in pure right sided heart failure due to delay in passage of the test substance from the arm vein to the lungs the lung to-tongue time (p 215) may be normal In pure left sided heart failure the arm to tongue time may be prolonged because of delay in circulation from the lung to the tongue while the arm to-lung time is normal The increase in circulation time or reduced speed of blood flow occurs in areas where there is a widening of the stream i e in the distended veins and the decompensated cardiac chambers without corresponding increase in quantity of blood flow But one must regard the reduced speed of blood flow as primarily due to a diminished driving force represented by the diminished cardiac output

The venous return to the heart is proportional to the circulating blood volume and to the speed with which this flows or inversely proportional to the circulation time Since the cardiac output is diminished in heart failure and the venous return is equal to the cardiac output the venous return is likewise diminished The increased circulating blood volume usually observed in heart failure would tend to augment the venous return if its speed of flow were unaltered However the fact that the venous return is reduced despite increased circulating blood volume denotes that slowing of the blood stream (increased circulating time) is more marked than increase in blood volume

In diseases associated with high cardiac output (arteriovenous fistula hyperthyroidism severe anemia et al) as well as during marked fever or exercise the circulation time is diminished or the speed of flow is increased[63] The venous return to the heart is augmented because of the increased speed of flow which outweighs any changes in circulating blood volume Accordingly the cardiac output is also enhanced With the occurrence of heart failure in the above diseases, the speed of the circulation falls but the circulation time may still be normal or slightly diminished Furthermore the circulating blood volume increases Hence the venous return (and likewise the cardiac output) is still

greater than normal since the blood volume is above normal and its speed of circulation normal.

FLUID AND ELECTROLYTES IN CONGESTIVE HEART FAILURE (see p. 275)

Fluid Retention and Abnormal Distribution

Excessive retention and abnormal distribution of fluids are striking features of congestive heart failure and appear to account for the major clinical manifestations. Almost identical clinical manifestations may occur in non-cardiac subjects who experience marked water retention following administration of steroid hormones, although there is no evidence of failure of the heart as a pump.[4] Although water diffuses freely through the membranes separating the blood vessels and cells from intercellular fluid, the total body water may be regarded as more or less quantitatively segregated into compartments, the intracellular and extracellular, and the latter further subdivided into the vascular and interstitial compartments. The relative integrity of these compartments is preserved by the membranes lining the blood vessels and cells—the vascular membrane by virtue of its relative impermeability to serum proteins and the cell membranes by similar impermeability to cell protein and by selective permeability to various electrolytes. The abnormal fluid retention that occurs in heart failure affects not only different body areas but also different fluid compartments in varying degree.

Although there are technical difficulties in the determination of total plasma, extracellular and intracellular water (see Chap. 10) and although these are magnified in heart failure because of the delay and uncertainty in obtaining uniform mixing of the injected test substance, reasonable approximations have been obtained.

Table 2 shows the distribution of body water in normal persons and in congestive heart failure for a body weight of 60 kg. Intracellular water, probably increased in heart failure, is assumed to be unchanged.

Table 2

	NORMAL		HEART FAILURE	
Compartment	Per cent body wt	Liters (Wt 60 kg)	Per cent body wt	Liters (Wt 70 kg)
Plasma	4.5	2.7	5.4	3.8
Interstitial	11.5	6.9	22.6	15.8
Extracellular	16.0	9.6	28.0	19.6
Intracellular	40.0	24.0	34.3	24.0
Total Body Water	56 [illegible]	33 [illegible]	62.3	43.6

Even without such determinations it is apparent that in advanced congestive heart failure vast quantities of water are retained in the extravascular extracellular fluid as revealed clinically by massive edema and large effusions in the serous cavities of the body. Various determinations of plasma volume have generally indicated a moderate increase of 10 to 50 per cent. Since the normal plasma volume in the adult is often only 2.5 to 3 liters, such increases as occur in heart failure, ranging from 0.5 to 1.5 liters, account for only a small part of the fluid retained. On the other hand, the remaining interstitial portion of the extracellular fluid (i.e., outside the blood vessels and outside cells) is commonly doubled or trebled in quantity and amounts in absolute terms to 15 or 20 liters instead of a normal of about 7 liters for an adult weighing 60 kg.

Changes in total body water may be estimated when there is a rapid weight gain in a patient developing congestive failure or more often when there is a rapid weight loss as a patient with heart failure is reduced to virtually dry weight by effective treatment. The increase in total body water is due essentially to increased extracellular water. Intracellular water, calculated by subtracting extracellular from total body water, cannot be determined with adequate accuracy in congestive heart failure. Direct determination of intracellular water on tissue biopsies of *skeletal muscle suggests that water is retained* within the intracellular as well as in other compartments.[106] Certain electrolyte and water balance studies made during recovery from heart failure[137, 103, 94, 1] also suggest that there is an increase in intracellular as well as extracellular water in congestive heart failure. *Water excretion during recovery from heart* failure has been found to be in excess relative to sodium, i.e., in comparison with the sodium concentration in serum, suggesting that water comes out of the cells during recovery from heart failure.[94, 103]

The changes in water distribution in the

various compartments in advanced congestive heart failure is indicated in Table 2. Perhaps the most striking finding is that the increase in interstitial fluid (edema) far exceeds the total plasma water. Therefore one cannot account for the edema by transudation from the blood stream due to elevated venocapillary pressure unless concomitantly there is some other mechanism for retention of water to replace the vast quantities lost from the blood stream to interstitial tissue.

In patients with right sided heart failure water retention is best observed in the lower extremities presumably owing to gravity and its hydrostatic effect in increasing capillary pressure. When the patient is recumbent edema of the lower extremities disappears or is alleviated and may then appear in the sacral region which is now the lowest part of the body. In patients with isolated left sided failure water retention is often not prominent and may *be difficult to demonstrate*. Nevertheless there is usually a delay beyond normal in excreting a water load.[80] Determinations of residual blood volume[112] and intrathoracic blood volume[54, 84] (p. 223) indicate that the increase in circulating blood volume is localized in large measure to the dilated, failing cardiac chambers and probably in the pulmonary circulation.

Sodium Retention in Heart Failure

It appears to be established that the abnormal retention of fluid in congestive heart failure is secondary to the abnormal retention of sodium ion. The integrity of the living cell is dependent on a constant osmotic pressure of the surrounding extracellular fluid which the body guards by various homeostatic mechanisms. The concentration of sodium ion in extracellular fluid is responsible for almost all the osmotic pressure due to cations and its constancy may be regarded as a measure of the constancy of the osmotic pressure. When the concentration of sodium in the blood increases the posterior pituitary gland is stimulated to secrete antidiuretic hormone, water is retained by the kidney and the normal concentration of sodium and the normal osmotic pressure is restored.[149, 114] This is the general manner in which it is assumed that the primary abnormal retention of sodium leads also to abnormal retention of water in congestive heart failure. But other mechanisms also are probably concerned in the regulation of water balance in congestive heart failure, for water may be retained even when the sodium concentration is below normal and the extracellular fluid is hypotonic.

That sodium and not water retention is the primary defect in heart failure is indicated by the common clinical experience that even a moderate intake of sodium by patients with heart failure increases clinical symptoms and results in rapid weight gain and edema due to fluid retention. On the other hand the intake of large quantities of water, except under unusual circumstances, does not increase edema and may even promote diuresis[1, 7] provided sodium intake is minimal. The rapid infusion of sodium-containing fluids or the oral ingestion of large amounts of sodium by patients with heart disease is frequently followed by the clinical picture of heart failure.[83, 119, 1, 2, 152] Conversely, striking relief of the symptoms and signs of heart failure has been effected by *maintaining an extremely low sodium intake*.[130]

The abnormal retention of sodium is also indicated by the inability of patients in heart failure to excrete a sodium load as do normal subjects. Futcher and Schroeder[53] injected 400 cc. of 6 per cent sodium chloride solution intravenously over a period of thirty minutes in patients convalescing from congestive heart failure. The renal excretion of sodium and chloride in the next twenty four hours was not more than 30 per cent of that observed in normal controls. Similarly Proger et al.[119] administered excessive amounts of sodium chloride by mouth to patients recently recovered from heart failure and observed an abnormal retention of sodium concomitant with the occurrence of their symptoms. That it is the sodium ion and not the chloride of sodium chloride which is responsible is indicated by the observation that the administration of other sodium salts is similarly associated with abnormal sodium and water retention, whereas chloride ion in the form of ammonium chloride does not cause a retention of salt or water and in fact produces a diuresis. Tracer studies with radiosodium (Na^{24} and Na^{22}) have shown an increase in total body sodium[1] as well as delayed excretion and retarded turnover of sodium during heart failure.[25, 146] The total body sodium is increased to 56.7 milliequivalents per kilogram of body weight instead of the normal

value of 35 2 milliequivalents per kilogram[150] The abnormal response of a patient in heart failure to a sodium load is indicated in the accompanying table

Table 3 Urinary Output of Sodium

After 500 cc of 5% sodium chloride (428 mEq) intravenously in 30 minutes in normal control and in patient with heart failure

INTERVALS AFTER IV Minutes	CONTROL Na Excreted mEq	% of load	HEART FAILURE Na Excreted mEq	% of load
140	101	23 6	12 4	2 9
310	51	11 9	10 3	2 4
750	105	24 5	12 5	2 9
Tot 1200 (20 hours)	257	60 0	35 2	8 2

Electrolyte Concentrations in Extracellular and Intracellular Fluid

The normal concentrations of the major extracellular and intracellular electrolytes are shown in Table 4

Table 4 Electrolyte Concentrations

	PLASMA[44] mEq /lit.	INTERSTITIAL FLUID mEq /lit	INTRACELLULAR mEq /liter cell water
Sodium	142	140	14[44]–37[28]
Potassium	4 5	4 5	106–112[3, 28]
Chloride	103	106	25[28]
Bicarbonate	27	28	10 (?)

Considerable uncertainty still exists as to the intracellular concentrations in normal individuals in heart failure this uncertainty is magnified due to technical difficulties especially the delay in obtaining complete homogeneous mixing of the injected test substance Determination of intracellular sodium and potassium concentrations is further complicated by the presence of large stores of these cations in bone[13] approximately 30 per cent of the body sodium has been estimated to be contained in bone and about 45 per cent of this is exchangeable[18] Dilution studies with radioisotopes have indicated that the intracellular concentrations of sodium and chloride are considerably greater than was previously thought and therefore that the cell membrane was not as impermeable to these ions as had been believed[88, 4, 3]

The concentration of electrolytes in the plasma and interstitial fluid in heart failure is usually relatively normal or only slightly altered Treatment with low sodium diets and mercurial diuretics is instituted so commonly before patients are hospitalized and their electrolytes studied that it is difficult to be certain whether or to what extent altered plasma electrolyte patterns are the result of heart failure or of the treatment Slight to moderate reductions in plasma sodium concentration are common possibly due to low sodium intake High plasma sodium concentration which might be expected on the basis of the abnormal sodium retention has been *reported*[118, 137, 77] *but is rare Despite low* sodium concentration *total body sodium* is quite elevated in heart failure[118, 150] since an approximate reduction of 7 per cent in plasma *sodium concentration* (e g from normal of 140 to 130 milliequivalents per liter in heart failure) is more than outweighed by an increase of 100 to 200 per cent in the extracellular fluid volume (plasma and interstitial fluid) containing this concentration of sodium Other changes in electrolyte pattern in heart failure due to mercurial diuretics other drug or renal or pulmonary complications are discussed in Chapter 11

Intracellular electrolyte changes in congestive heart failure have been reported on the basis of direct analysis of cardiac and skeletal muscle post mortem[7, 45] and of biopsy specimens of skeletal muscle in vivo[106, 115] on the basis of balance studies during recovery from heart *failure*[74, 103, 137, 81] *and during mercurial diuresis*[47, 137] and by isotope dilution techniques[131, 4] Although the findings are not uniform in general these varied studies indicate that in congestive heart failure there is an increase in intracellular water and sodium and a diminution in intracellular potassium In cases of heart failure due to cor pulmonale there may be a cellular loss of water and sodium as well as of potassium[95] Determination of intracellular water and electrolytes by tissue analysis is especially difficult in the presence of tissue edema in heart failure Reduction in electrolyte concentration may also be due to dilution by tissue edema rather than to absolute reductions Striking transfers of sodium potassium and water between the extracellular

and intracellular compartments appear to occur during the development of and during the recovery from congestive heart failure Iu k and Palmer[94] observed that when a patient who had recovered from heart failure was given fairly large quantities of sodium expansion of the extracellular fluid space and clinically manifest heart failure did not occur until after the intracellular space was saturated with sodium The realization that cells are more readily permeable to sodium and chloride than was previously recognized and that a considerable percentage of bone sodium is readily exchangeable may invalidate some of the earlier calculations in balance studies

It is obvious that a greater knowledge of the intracellular electrolytes and their behavior in congestive heart failure would be valuable in understanding the sequence of events leading to the clinical picture of congestive heart failure The renal retention of sodium and water may be initiated by intracellular water and electrolyte disturbances caused when the cardiac output becomes deficient and interferes with normal cellular metabolic processes Since recent studies with radioisotopes have shown a rapid exchange of sodium ions across cell membranes and a higher cellular concentration of sodium than was previously thought our concept of cell membrane impermeability to sodium has undergone revision According to one theory [70] [8] sodium ions enter the cell readily but a mechanism of carrier molecules acts as a ' pump to extrude from the cell most of the sodium that diffuses into it The energy for such work is conceived as being supplied by intracellular reduction and oxidation reactions The energy is transferred to carrier enzymes which combine with sodium ion and carry it to the cell membrane for extrusion out of the cell Balancing of sodium outflow by potassium inflow maintains both electrical neutrality and normal intracellular osmolarity

It is of interest that the retention of water and sodium and loss of potassium by the cells in heart failure are similar to the increased sodium and water content and loss of potassium by skeletal muscles during contraction and to the release of cellular potassium and increase in sodium associated with membrane depolarization by a nerve impulse It may be speculated whether cardiac failure with its deficient blood flow disturbs the mechanism of energy production or energy transfer in cells, thereby impairing the pump mechanism for intracellular electrolyte balance Such disturbance whether localized in all cells or predominantly in renal tubule cells could be concerned with the abnormal renal retention of sodium and water in congestive heart failure

Mechanism of the Abnormal Renal Retention of Sodium in Heart Failure

Not only is there uncertainty as to the intermediate steps between cardiac failure and the abnormal retention of sodium and water by the kidney but there is also disagreement as to the renal mechanism responsible for the sodium water retention Three mechanisms have been considered (1) elevation of renal venous pressure due to congestive heart failure, (2) diminution in glomerular filtration of sodium and water possibly due to reduced renal arterial blood flow (3) increased tubular reabsorption of sodium and water due to chemical hormonal or other influences

1 **Elevated Renal Venous Pressure** Sodium water retention by the kidney has been attributed to an elevated renal venous pressure and passive congestion of the kidney [88] An elevated venous pressure has been found by catheterization of the renal vein of patients with heart failure[94] these patients also had an elevated right atrial pressure denoting right sided heart failure Partial occlusion of one renal vein in dogs caused a diminution in sodium and water excretion only from the kidney subjected to an increased renal venous pressure (above 150 mm saline) [158] The disturbances in sodium water excretion appeared without distinct relation to changes in renal blood flow or glomerular filtration

In the experimental production of chronic pericarditis with effusion a reduction in renal output of water and sodium is associated with a rise in venous pressure even though resting cardiac output renal blood flow and glomerular filtration are at control levels [45] These acute experimental observations appear to support the theory that heightened renal venous pressure in heart failure impairs the renal excretion of sodium and water On the other hand more prolonged experimental elevation of renal venous pressure by partial ligation of the inferior vena cava in trained unanesthetized dogs disclosed an initial diminution in sodium excretion glomerular filtration and renal plasma flow but after a week

these had returned or were returning to normal even though the venous pressure was still elevated[75] Although prolonged inferior vena caval ligation *below* the diaphragm but including the renal vein was not followed by sustained retention of sodium and water prolonged experimental constriction of the inferior vena cava *above* the diaphragm, which caused congestion of the liver as well as of other abdominal viscera, led to sustained edema and ascites[1 3] Furthermore, by use of an intracardiac catheter with inflatable balloon it has been demonstrated in humans that not only elevation of renal venous pressure but also obstruction and venous congestion of the superior vena cava or of the inferior vena cava below as well as above the renal veins diminished the renal excretion of sodium and water[43]

It is questionable whether these experimental observations which do not duplicate the findings in chronic congestive heart failure in humans apply to the mechanism underlying the abnormal retention of sodium and water in heart failure But even if elevated renal venous pressure does diminish the excretion of sodium and water, it could not represent the initial cause for the renal impairment in heart failure because sodium and water retention occur in left sided heart failure before there is any elevation in systemic or renal venous pressure It is possible that elevated systemic or renal venous pressure may intensify the renal disturbance later in the course of heart failure when the right ventricle becomes insufficient and the systemic venous pressure rises

Table 5 Renal Hemodynamics in Congestive Heart Failure (After Heller and Jacobson[81])

	NORMAL	HEART FAILURE
Glomerular filtration rate cc /min	103	75 (54–105)
Renal plasma flow cc /min	603	190 (19–313)
Filtration fraction	0 174	0 323

2 Diminished Glomerular Filtration The studies of Merrill[100] and of Mokotoff, Ross and Leiter[105] and others[83] disclosed a reduction in renal blood flow and in the excretion of sodium and water in patients with congestive heart failure Renal blood flow was diminished more than cardiac output, indicating renal vasoconstriction Renal plasma flow was reduced more than glomerular filtration resulting in an increased filtration fraction, presumably due to constriction of the glomerular efferent arterioles Mokotoff et al[105] concluded that the retention of sodium was due to diminished glomerular filtration consequent to the diminished renal blood flow, and not to increased tubular reabsorption Tubular reabsorption was found to represent a constant percentage of the glomerular filtrate

But it should be recalled that great variations in the glomerular filtration of sodium and water are easily neutralized by small deviations in tubular reabsorption Normally about 99 5 per cent of the sodium and water in the glomerular filtrate is reabsorbed by the tubules A reduction of 50 per cent in glomerular filtration could be neutralized and a normal sodium excretion effected if the tubular reabsorption diminished merely from 99 5 to 99 0 per cent To attribute the impaired sodium excretion to reduced glomerular filtration alone it is necessary to prove that tubular reabsorption is absolutely unchanged But in one of the patients studied by Merrill[100] 99 99 per cent of the sodium filtered by the glomeruli was reabsorbed and in another 99 96 per cent instead of the normal 99 5 per cent Similarly the figures of Mokotoff et al[105] strongly suggest that tubular reabsorption is increased despite their conclusions to the contrary I have observed instances in which no sodium was excreted during whole days in patients with congestive heart failure[81] Significant variations in tubular reabsorption, sufficient to cause considerable retention of sodium are of such small magnitude that they could easily be obscured by the range of error of the methods now available

Other objections have been raised to the belief that renal impairment of sodium and water excretion is due entirely or primarily to *diminished glomerular filtration* Glomerular filtration is diminished in essential hypertension but there is no significant renal retention of sodium and water Edema does not occur in many cases of intrinsic renal disease in which glomerular filtration is substantially reduced This has suggested that a glomerulo-tubular imbalance rather than defective glomerular filtration alone causes sodium water retention and edema In occasional cases of congestive

heart failure an impairment of renal excretion of sodium and water is observed although glomerular filtration is normal[135] Patients in heart failure have been observed to regain clinical compensation without a significant augmentation of their glomerular filtration rate[133 1 135 21] although the ability to excrete sodium was restored

It appears that reduction in glomerular filtration of the degree commonly observed in congestive heart failure results in a significant diminution in sodium excretion, provided tubular reabsorption remains normal or increases But it is improbable that this is the sole or essential factor in the abnormal retention of sodium and water by the kidney in congestive heart failure

3 **Increased Tubular Reabsorption** . Abnormal renal excretion of sodium in heart failure may be due to increased tubular reabsorption[44 135] This is suggested by our knowledge that the tubules are important in the regulation of sodium metabolism especially in maintaining the pH the isotonicity and the volume of body fluids Tracer studies with radioisotopes of sodium led Burch Reaser and Cronvich[-] to conclude that diminished sodium excretion was due to an increased percentage of reabsorption of this electrolyte from the glomerular filtrate The instances in which I have observed no excretion of sodium at all for twenty four hour periods also support this conclusion The ability of many patients to maintain sodium balance despite impaired glomerular filtration indicates that the percentage of tubular reabsorption of sodium can be regulated independently of filtration[59] On the other hand it has been postulated that there is a threshold or limited transfer mechanism for sodium reabsorption in the distal tubule Thus with increased sodium filtration the distal tubular reabsorptive capacity may be exceeded and more sodium is excreted with diminished glomerular filtration the small load reaching the distal tubule may be virtually entirely reabsorbed According to this view increased tubular reabsorption is determined by impaired glomerular filtration

Indirect evidence of the importance of exaggerated tubular reabsorption of sodium rather than diminished glomerular filtration in heart failure is provided by studies of renal hemodynamics during and after exercise Kattus Sinclair Smith and associates[8] found that exercise produced sodium retention in normal individuals without alteration of filtration rate and in patients with congestive heart failure exercise produced sodium retention with or without reduction in glomerular filtration Furthermore, when filtration was diminished it returned to normal after cessation of exercise while sodium retention was still present

Experimental studies with sodium loading also suggest that diminished sodium excretion in heart failure is due to increased tubular reabsorption Barger Rudolph and Yates[7] measured renal clearances following intravenous infusions of sodium chloride in dogs with mild heart failure due to experimentally produced valvular lesions While renal plasma flow and glomerular filtration rose to a normal degree after the infusion sodium and water excretion were decreased as a result of more complete tubular reabsorption

Mechanisms Increasing Tubular Reabsorption of Sodium

Excessive tubular reabsorption of sodium and water in heart failure may be mediated through the secretions of endocrine organs, notably the anterior pituitary or adrenal cortex, through other humoral agents or by local changes in tubular cellular metabolism

Adrenal Cortical Hormones The adrenal cortex has been assigned a primary role in the regulation of sodium and water chiefly by endocrine regulation of tubular reabsorption of sodium The adrenal cortical hormones desoxycorticosterone and aldosterone are powerful sodium retaining factors To a much lesser extent ACTH cortisone and hydrocortone cause an early renal retention of sodium despite the fact that there is a rise in glomerular filtration Unless sodium intake is sharply restricted their administration may cause edema pulmonary edema, and in fact many of the hemodynamic disturbances usually associated with congestive heart failure[8] Similarly desoxycorticosterone, which probably acts on the tubules is capable of inducing heart failure when given in excess to patients with Addison s disease These similarities have suggested that the secretion of adrenal corticoid hormones may actually represent an intermediate mechanism in heart failure whereby the renal tubules are influenced to abnormal retention of sodium and water and the production of the clinical features found in heart failure

There is considerable evidence that various

stresses or threats to bodily homeostasis evoke reactions by way of the adrenal cortex Failure of the heart may represent such a stress with a corresponding adrenal cortical response An increased amount of urinary corticoids[115] and the sodium retaining corticoid, aldosterone[93, 5] have been found in the urine of patients with congestive heart failure[138] The reduction of sodium output in the sweat[100] saliva[15] and feces[12] as well as in the urine of patients with heart failure suggests that abnormal sodium retention in heart failure is not a local renal effect but rather the consequence of adrenal cortical action on multiple sites including the renal tubules The exact stimulus to the hypothesized excessive adrenal cortical activity is unknown Since impairment of liver function is common in chronic congestive heart failure it has been suggested that the liver is deficient in its inactivation of adrenal corticoids But this mechanism would not apply to isolated left heart failure

Antidiuretic and Other Hormones The renal retention of water rather than sodium per se causes many of the outstanding features of heart failure but the water retention is regarded as secondary to retention of sodium The latter in turn stimulates the hypothalamic posterior pituitary axis to secrete antidiuretic hormone (ADH) which acts on the distal tubule to inhibit the excretion of water without directly affecting that of sodium The water retaining effect of ADH results in a more concentrated urine of diminished volume but the absolute quantity of sodium in the urine is unchanged[7] Therefore ADH is *not regarded as a primary factor in the accumulation of excessive fluid in congestive heart failure*

Bercu and associates[10] found an antidiuretic substance in the urine of 12 of 15 patients with cardiac edema Similar antidiuretic substances have been discovered in the urine of patients with cirrhosis of the liver toxemia of pregnancy and Cushing's disease But the finding of antidiuretic pitressin like substances in the urine in states associated with abnormal sodium water retention such as cirrhosis of the liver and congestive heart failure may be interpreted as the secondary consequence of disturbances in fluid and electrolytes in these conditions rather than as the initiating factor Since the liver normally inactivates ADH the accumulation of antidiuretic substances may be the result of liver dysfunction in cirrhosis and in heart failure[15] But recent studies have indicated that ADH is normally inactivated in patients with cirrhosis of the liver[14, 167]

It is of interest that the continued intramuscular administration of long acting pitressin in oil to patients with congestive heart failure produces a clinical picture resembling refractory heart failure until the hormone is discontinued[15] And in patients with low sodium concentration in the plasma and a clinical picture of intractable heart failure, abnormal retention of water occurs even when there is no positive sodium balance Since other factors besides dehydration and increased osmotic pressure evoke the secretion of ADH[III] the abnormal retention of water in heart failure or certain stages of heart failure may be initiated through other mechanisms besides sodium retention[III] This is strikingly indicated by retention of water instead of its diuresis in certain patients with heart failure despite a low sodium concentration and consequent reduced osmolarity of the extracellular fluid Antidiuresis may thus be stimulated by other factors besides extracellular hypertonicity, perhaps an inadequate effective blood volume[87] or cardiac output

Other hormones and humoral agents have been implicated as possible factors in the diminished renal excretion of sodium and water Vasoexcitor material (VEM)[87] and renin[10] have been found in the renal venous blood and vasodepressor material (VDM) in the hepatic venous blood of patients with congestive heart failure[87] However there is no evidence that these substances are concerned with the formation of edema in heart failure

Cellular Changes in Renal Tubules The renal tubule cells perform work in the reabsorption of sodium from the tubule lumina Cellular metabolic processes and enzymes such as carbonic anhydrase and succinic dehydrogenase are concerned with the production of energy and its utilization in the performance of sodium reabsorption Our knowledge of these processes is still too primitive to permit an answer as to the possible action of heart failure on the renal tubule cell, either by its effect on the renal blood flow or oxygen supply or by some other means

Exercise and Renal Excretion of Sodium

Exercise is the commonest stress in the normal individual Exercise produces a

prompt retention of sodium and water in the normal individual and unless the exercise is severe there is little or no change in renal hemodynamics[134] (But see also Freeman et al[43]) Sodium and water retention may be regarded as an adjustment to body stress such as that represented by exercise Sodium water retention occurs in patients with heart failure even when they are at rest but the retention is greatly magnified by exercise[16] [redacted] Because of the qualitative similarity of the sodium water retention with exercise and in heart failure a similar mechanism has been sought for both[116] However the mechanism by which exercise produces renal retention of sodium and water either in the normal person or in the patient with heart failure is still conjectural It is to be noted that sodium excretion diminishes with exercise although the cardiac output increases But the sodium retention may indicate that though the cardiac output is increased it is at least temporarily inadequate for the augmented needs of the exercising muscles

Possible Stimulus and Receptor Sites for Renal Retention of Sodium and Water

Not only [redacted] there uncertainty as to the particular *renal mechanism* responsible for abnormal retention of sodium and water but there is an equal lack of understanding as to the stimulus which induces such retention Among the *possible* stimuli initiating such retention the following have been considered (1) inadequate cardiac output (2) diminution in effective circulating blood volume (3) diminution in cerebral blood flow (4) increased volume and pressure in various possible receptor areas of the venous system (5) redistribution of blood from the arterial to the venous side (6) diminished mixed venous oxygen concentration (7) anoxia of various body cells or of renal tubule cells

Renal retention of sodium is induced in a variety of physiologic conditions and abnormal states other than congestive heart failure[29] In normal persons the erect posture[41] sitting[149] or tilting the body toward a head up position[11] and exercise[135] result in a diminution in sodium and water excretion Sodium retention has also been observed following the application of tourniquets to the four extremities or to the thighs alone[158, 169, 73, 46] and following obstruction and venous congestion at various sites of the inferior and the superior vena cava, previously discussed[16, 75, 5] [redacted] (p 171) These varied observations have been interpreted by different observers to indicate that retention of sodium and water is stimulated either (1) by a reduction in effective blood volume due to pooling of blood in the lower extremities or other body areas with consequent transudation of plasma water out of the capillaries (2) by a reduction in cardiac output since reduction in effective blood volume is translated into reduced venous return and cardiac output or (3) by diminished cerebral blood flow due to diminished cardiac output or cerebral vasoconstriction such as occurs when an individual is in the upright position[116] Bleeding of normal dogs[81] or the occurrence of hemorrhage in pathologic states[19] is associated with a decline in sodium excretion which could be attributed to diminished effective blood volume or cardiac output

The above mentioned changes in excretion of sodium and water with postural changes the application of venous tourniquets and obstruction of various sites of the caval systems have suggested that changes in volume and pressure in some local area of the venous circulation might serve as the stimulus to renal retention of sodium and water Such a site might represent a volume regulator i e [redacted] regulator of the circulating blood volume besides that of the hypothalamic pituitary axis Lewis and associates[80] observed that in normal subjects in the sitting position compression of the neck by a blood pressure cuff inflated to 20 mm Hg or more induced a marked increase in sodium excretion but this did not occur in patients with heart failure[8] These findings suggested that the brain contained the receptor site for the regulation of volume by modifying the renal excretion of sodium and water and that this regulator was defective in a patient with heart failure because of a more powerful mechanism favoring sodium retention Compression of the legs by elastic bandages resulted in increased sodium excretion which was attributed to a redistribution of blood or extracellular fluid resulting in stimulation of a volume-regulating receptor area in the cranial cavity[117] On the other hand no further increase in sodium excretion occurred when the head was tilted after neck compression in subjects who were sitting and no increase in sodium excretion occurred when the neck was compressed in recumbent subjects Netravisesh[103] was unable to confirm

the reported findings of increased sodium excretion following compression of the neck

Observations in cases of high-output failure and notably in arteriovenous fistula, suggested that sodium retention may be stimulated by a redistribution of blood from the arterial to the venous side When an arteriovenous fistula is closed the high cardiac output is diminished but the excretion of sodium is increased This appears to contradict the theory that a fall in cardiac output diminishes sodium excretion But one may maintain that the high output in arteriovenous fistula is inadequate for tissue needs, whereas the lower cardiac output which occurs when the fistula is closed provides a more adequate supply of blood for the tissues How the kidneys sense that the higher output is inadequate and therefore retain sodium and water is unknown It seems that the initial stimulus must arise in the area of the body distal to the fistula which at first fails to obtain its needed blood flow because of the shunting of blood or because of venous congestion of that area It has also been suggested that the lowered peripheral resistance in arteriovenous fistula permits easier egress from the arterial to the venous system with a redistribution of the circulating blood volume in favor of the venous side This redistribution of blood to the venous side has been postulated to be the stimulus for retention of sodium and water in arteriovenous fistula as well as after postural change to the upright position, after the application of tourniquets and presumably in congestive heart failure[4]

In patients with low cardiac output the arterial oxygen concentration is usually normal but the oxygen concentration of mixed venous blood is diminished Renal retention of sodium and water has been related to the latter presumably because a diminished oxygen content of venous blood denotes a deficiency in oxygen supply or oxygen tension in the tissues However in high-output heart failure sodium retention occurs even though the oxygen content of mixed venous blood is higher than normal Thus sodium retention cannot be related to the *absolute* value of the mixed venous oxygen On the other hand the mixed venous oxygen is lower after heart failure in conditions of high cardiac output than it is before failure occurs

Hypoxia of various body cells would appear to be a plausible stimulus for sodium retention since hypoxia seems to be a consequence of the inadequate cardiac output which characterizes congestive heart failure However acute experimental hypoxia does not reduce the glomerular filtration rate in normal subjects nor does it further diminish the low filtration rate in patients with congestive heart failure[11] In fact breathing a low oxygen mixture caused an *increase* in sodium excretion[11] However, it is questionable whether the degree and brief duration of the experimental hypoxia duplicate the conditions of possible mild chronic cellular hypoxia in heart failure Furthermore the increased excretion of sodium may be due to hyperventilation induced by breathing air with low oxygen concentration

Hypoxia of the liver in heart failure has been invoked as a possible mechanism to account for water retention Vasodepressor material (VDM) is formed by the liver as a result of hypoxia in the experimental animal and produces antidiuresis by stimulating the posterior pituitary to secrete antidiuretic hormone Hypophysectomy abolishes the antidiuretic effect of VDM

Hypoxia or other disturbances associated with heart failure may alter cellular metabolism or cellular osmolarity There is evidence that alterations in cellular osmolarity may initiate renal mechanisms responsible for electrolyte and water retention[13, 154, 93]

The various observations mentioned above do not permit a definite choice of stimulus or mechanism responsible for the retention of sodium and water in heart failure Many of the experimental observations on sodium water retention have dubious applicability to the problem in congestive heart failure Differences in acute versus more prolonged experiments suggest caution in utilizing the experimental findings to interpret mechanisms in a chronic state such as congestive heart failure There is some doubt whether the stimulus to sodium water retention in patients with heart failure is the same as that in normal individuals That certain changes in sodium and water excretion occurring with change in posture and with compression of the neck are not observed in patients with heart failure[30, 37] has already been mentioned Another difference concerns the diurnal variation in sodium water excretion In normal persons maximum excretion of sodium and water occurs during the day in patients with heart failure during the night[37] Whereas

venous congestion of the legs or a phlebotomy of 450 to 700 cc of blood decreased sodium excretion in normal individuals they had variable effects on sodium excretion in patients with congestive heart failure[79] There was some evidence that the diminished unchanged or increased sodium excretion in these experiments was related to corresponding changes in cardiac output[80]

For the present this writer favors the theory that in heart failure the abnormal renal retention of sodium and water is the consequence of an inadequate cardiac output[11, 43, 44] This may act by causing anoxia of the liver of the pituitary and adrenal cortex of the renal tubule cells or of other organs or by disturbing volume and pressure relations in various segments of the venous system A reduction in effective blood volume is significant only insofar as it impairs the adequacy of the cardiac output Maintenance of a normal cardiac output is apparently carefully guarded by bodily homeostatic mechanisms[43] In heart failure the retention of sodium and water by the kidneys may represent a compensatory mechanism for restoring the cardiac output by increasing the circulating blood volume and venous return This hypothetical statement is not invalidated by the fact that the compensatory mechanism may itself be responsible for clinical symptoms for example many of the clinical features of shock are due to compensatory vasoconstriction secondary to diminished cardiac output More definite understanding of the mechanism responsible for sodium water retention in heart failure must probably await better knowledge of intracellular metabolism and especially of intrinsic mechanisms whereby tubule cells regulate the excretion of water and electrolytes

THEORIES OF MECHANISM OF HEART FAILURE

THE BACKWARD FAILURE THEORY

The backward failure theory maintains that the clinical manifestations of congestive heart failure are due to passive engorgement of the venous tributaries caused by a backward rise in pressure upstream from (i e proximal to) the failing cardiac chambers[81]

The backward failure theory was based on (1) experimental studies of the circulation (2) pathologic observations and (3) clinical observations

Correlation of Experimental Circulatory Studies with Backward Failure Theory

The studies of Starling[135] Straub[143] and others on the heart lung preparation and with similar experimental circulatory set-ups showed that the important cardiac and circulatory disturbances occurred *behind* the experimental obstruction or lesion while the abnormalities in front of or downstream from the lesion were only temporary and rapidly compensated (Chapter 4) Thus when the outflow from a cardiac chamber is obstructed or when the heart begins to fail the cardiac output is only slightly and temporarily diminished The affected chamber dilates contracts more forcefully because of the consequent lengthening of the cardiac fibers and thereby restores the normal output The venous pressure remains normal This corresponds to the clinical state of compensated heart disease

With increasing fatigue of the heart the pressure within the cardiac chambers becomes so elevated that the venous return to the heart is embarrassed Now the venous pressure rises i e backward from the heart This corresponds to the clinical stage of congestive heart failure With fatigue of the chambers on the left side of the heart as with experimental aortic and mitral valvular lesions there is an increased resistance to inflow into the left atrium The venous pressure rises in the pulmonary veins and their tributaries in the lungs This corresponds to left sided heart failure With severe experimental mitral stenosis there is a rise of pressure in the pulmonary artery This places a strain on the right ventricle Its intraventricular pressure rises to overcome pulmonary arterial resistance Eventually this rising pressure is transmitted backward until the venous pressure in the venae cavae and their tributaries is elevated This corresponds to right sided heart failure

The increased venous pressure according to Starling[135] promotes cardiac filling by maintaining a pressure difference between the great veins and the atria This rise in venous pressure serves as a compensatory mechanism by which the cardiac output is maintained at relatively normal or slightly diminished levels These and similar observations with

individual experimental valvular lesions were interpreted to indicate that the sequence from earliest cardiac fatigue to frank heart failure is characterized by a rising pressure in the cardiac chambers retrograde from the site of disturbance into the venous system Recent determinations, by intracardiac catheterization, of the venous pressure and of the pressures within the cardiac chambers of patients with heart failure have confirmed these pressure changes as postulated by the backward failure theory For in left sided heart failure there is a pronounced elevation in left atrial pulmonary venous capillary and arterial pressure and in right ventricular systolic and pulse pressure, in right sided heart failure there is an elevation of the right ventricular diastolic pressure the right atrial and the peripheral venous pressure[9] (p 165)

Pathologic Support for Backward Failure Theory

Pathologic observations indicate that heart failure is characterized by venous congestion involving the organs proximal or behind the failing chamber and not by ischemia in front of or distal to that chamber In cases of left ventricular heart failure only or predominantly the lungs show evidence of capillary and venous congestion as if there were "back pressure" from the failing left chambers In cases in which the right ventricle fails, the capillary and venous congestion is located in organs which would experience a rise in venous pressure "backward" from the right side of the heart viz the liver spleen intestines kidneys skin and so on Furthermore, the symptoms and signs of congestive heart failure appear to arise in these sites of venous congestion

Clinical Observations Supporting Backward Failure Theory

The backward failure theory appears to conform with the observation of isolated left and isolated right ventricular failure and with the usual sequence of development of the individual symptoms of left- and right sided failure Thus if the left ventricle fails and the right is competent the venous congestion is localized in back of the left chambers, i e in the lungs the elevated venocapillary pressure is localized to the lungs and the only symptoms are those referable to pulmonary congestion namely dyspnea orthopnea cardiac asthma, pulmonary edema and cough The systemic venous pressure is not elevated and there are no symptoms referable to systemic venous congestion Similarly, there may be isolated right ventricular failure with venous congestion, elevated venous pressure and corresponding clinical features confined to organs drained by systemic veins

If the clinical features of heart failure were due exclusively directly or indirectly, to forward failure i e to an inadequate cardiac output, failure of the left ventricle should lead either to symptoms referable to organs supplied by the left ventricle (e g , brain extremities abdominal viscera, but not the lung) or to symptoms referable to both the systemic and pulmonary circulation

Finally in the common forms of heart failure due to coronary artery disease, hypertension or aortic and mitral valvular disease the sequence of development of symptoms appears to support the backward failure theory The first symptom is breathlessness which may be related to congestion of the lungs Later as pressure rises not only in the pulmonary vessels but in the right ventricle, the latter fails the right ventricular diastolic the right atrial and the systemic venous pressures rise (in a backward sequence from the failing chambers) and the symptoms of right ventricular failure appear

THE FORWARD FAILURE THEORY

The fundamental basis for the forward failure theory is the presence in heart failure of an inadequate cardiac output Formerly this theory explained symptoms and signs in each individual organ as the direct consequence of insufficient blood to that organ In its more recent form, symptoms of congestive heart failure are attributed only in part to inadequate blood flow to individual organs but *chiefly to a renal retention of sodium and water* because of inadequate blood flow to the kidneys Emphasis is placed on a prolonged deficiency of cardiac output relative to the requirements of the tissues rather than on an absolute diminution in cardiac output[141] The cardiac output may be adequate when the patient is at rest and he is asymptomatic, yet during activity the output may even increase but is inadequate for the increased bodily demands and symptoms of heart failure appear In the presence of advanced heart failure symptoms such as weakness and fatigability, believed to result directly from inadequate blood flow (to the muscles) are masked by

dyspnea, orthopnea and edema believed to result indirectly from impaired renal excretion of sodium and water. When the latter symptoms are alleviated by the restriction of sodium and by the administration of mercurial diuretics, weakness and fatigability may become more apparent.

The forward failure theory is supported by the usual finding of a diminished cardiac output, by the finding of a diminished renal blood flow, by the impairment of renal excretion of sodium and water and by the fact that the clinical phenomena of congestive heart failure are dependent on an abnormal retention of sodium and water. According to the forward failure theory, the impaired renal excretion is related to the diminished cardiac output and consequent reduction in renal blood flow. Merrill[100] found that the renal blood flow in patients with heart failure was reduced to one third to one fifth of normal. Since the reduction in renal blood flow was greater than the reduction of cardiac output, there appeared to be a specific diversion of blood away from the kidney. Other studies confirmed these findings and disclosed that the glomerular filtration rate was also reduced but not as much as the renal blood flow. Diminution of renal blood flow and glomerular filtration was related to the degree of reduction in cardiac output but bore no relation to the venous pressure; these findings were interpreted to support the forward failure and not the backward failure theory.

Elevated Venous Pressure Versus Renal Retention of Sodium and Water

A large measure of the disagreement between the proponents of the backward failure and of the forward failure theories concerns sequence of development and the relative importance of renal retention of sodium and water as compared with the elevation of venous and capillary pressure in the production of edema and other cardinal symptoms of heart failure. The occurrence and severity of edema cannot always be correlated with the presence or degree of elevation of venous pressure. On the other hand, an elevated venous pressure at rest or with mild exercise is the rule in heart failure associated with edema.

Observations by Warren and Stead[15] on the appearance of heart failure were interpreted to indicate that salt and water retention in the body tissues precedes the development of an elevated venous pressure. They administered 9 to 12 gm of sodium chloride by mouth to patients recently recovered from heart failure and made daily observations of weight and frequent observations of the venous pressure. A significant weight gain, presumably due to salt-water retention, occurred when the venous pressure was still normal; elevation of venous pressure occurred a few days later. Similar observations were reported by Goldman and Bassett.[illegible] However, the findings could also be interpreted to support the backward failure theory, for the water retention causing weight gain could have first been limited to the left heart chambers and pulmonary circulation, and there may have been a rise in pulmonary venous pressure before a rise in systemic venous pressure was apparent. Furthermore, it is often difficult to distinguish a time difference in the development of elevated venous pressure and gain in weight due to sodium water retention, both apparently occurring virtually simultaneously.[240, 111]

When digitalis is withdrawn from a patient with heart failure on a low sodium intake, the venous pressure rises without an accompanying gain in weight.[111, 121] These observations likewise cannot be interpreted to support the primary importance of either elevated venous pressure or sodium water retention in heart failure. The use or discontinuation of a therapeutic agent can modify one or the other of these factors. When digitalis is withdrawn from a patient whose symptoms of heart failure are under control and who is receiving a minimal quantity of sodium, there is a further deterioration of cardiac function resulting in a further reduction of the cardiac output. This may lead to an elevation of venous pressure because the undigitalized deficient heart can no longer accept and eject the venous return. On the other hand, weight gain and edema may not occur because the sodium water retention necessary to its formation is artificially inhibited by the low sodium intake.

CRITICISMS OF BACKWARD FAILURE AND FORWARD FAILURE THEORIES

There can be no "backward failure" without "forward failure" in a continuous circulation. Hence the contrast of terms should be abandoned. The term "backward failure" is a confusing one in that it implies a *direction* of flow when actually it refers to a sequence of *locations* of venous congestion. Even if the

symptoms of heart failure appear to be due to venous congestion and rising pressure behind a failing chamber the backward failure theory omits a series of preceding or almost simultaneous events, including the renal retention of sodium and water, which occurs after the initiation of heart failure and without which such congestion could neither occur nor persist Heart failure could not produce a persistent rise in pressure behind the failing chamber unless simultaneously or very soon thereafter there occurred an increase in circulating blood volume Starr et al[140] observed only a slight increase in venous pressure following acute and chronic damage to the dog s right ventricle Starr[139] also noted that immediately after death the static blood pressure in the heart and vessels, i e in the absence of the heart beat was three times as high in subjects who had died of heart failure as in those without heart disease These observations were interpreted to indicate that the venous congestion and elevated venous pressure in heart failure were due not to stasis behind the weakened chamber but essentially to increased blood volume in the distensible veins and to venoconstriction

The forward failure theory does not satisfactorily account for inconsistencies between the cardiac output and the occurrence and severity *of symptoms of congestive heart* failure Sodium retention cannot always be correlated with reduction in cardiac output and with reduction in renal blood flow Sodium water retention per se does not account for the localized rise in venous pressure in the pulmonary circulation in left sided heart failure and in the systemic veins in right sided heart failure Warren and associates[151] noted that shortly after the intravenous injection in dogs of normal saline in an amount equal to body weight, over a period of six to eight hours the extracellular fluid volume was more than doubled but the blood volume and venous pressure were virtually unchanged This suggests that a persistent increase in blood volume and in venous pressure does not follow increased sodium and water intake unless heart failure is present The forward *failure theory does not clearly* account for the occurrence of isolated left-sided heart failure or for the sequence of development of symptoms in progressive left sided and subsequent right-sided heart failure Finally, the clinical picture which characterizes a definite fall in cardiac output is that of shock, not that seen in congestive heart failure

THE MECHANISM OF CONGESTIVE HEART FAILURE

On the basis of the observations of changes in hemodynamics and in electrolytes and fluid in congestive heart failure described in the preceding portion of this chapter the following mechanism of heart failure appears most probable But it must be stressed at the outset that there are still many important gaps in our knowledge and that any theory of heart failure at the present time suffers from considerable speculation

Initial Disturbances in Heart Failure

When a chamber fails it no longer ejects as much blood as it normally does with a given inflow Consequently, the output is diminished and the blood residual in the chamber is increased The end diastolic pressure rises Elevated ventricular diastolic pressure is associated with corresponding elevation of atrial and venous pressure While deficient emptying of the failing chamber may be followed by temporary increase in these pressures the maintenance of these increases depends on mechanisms which are uncertain at *the present time Otherwise, the falling output* would result in a lower arterial pressure diminished venous return and eventual reduction of the venous atrial and ventricular diastolic pressures The diminished cardiac output, the elevated pressure in the failing chamber or the elevated venous pressure may initiate mechanisms which maintain the elevated pressures and the disturbances in blood flow and distribution of water and electrolytes which characterize heart failure

These mechanisms may be regarded as homeostatic mechanisms which restore the cardiac output when this tends to become inadequate because of physiologic or pathologic disturbances In congestive heart failure an augmented circulating blood volume serves to restore the cardiac output when the fall in output is moderate and sufficient time elapses to *permit the development of this compensatory* mechanism *The symptoms of congestive heart failure are due in large measure to difficulties imposed by the compensatory mechanisms and not directly to a deficient output* hence there is

no close correlation between the cardiac output and severity of symptoms except in advanced cases

Homeostatic Mechanisms Controlling the Cardiac Output

The fundamental function of the heart is to maintain an adequate output of blood for the tissues under all physiologic circumstances. When the heart fails a variety of compensations are evolved which tend to restore this vital function. Consequently the cardiac output is maintained long after serious circulatory threats and disturbances arise just as the pH of the blood remains constant despite disorders threatening its acid base balance and just as the blood urea remains normal even when there is moderately severe renal impairment

The following compensatory mechanisms may restore a deficient cardiac output or may otherwise serve to maintain an adequate blood supply to vital organs

1 *Tachycardia and Cardiac Enlargement* These accommodative mechanisms which increase the cardiac output have been previously discussed (Chapter 4) Like all compensations cardiac enlargement is valuable in that it preserves a vital function in this instance a normal cardiac output It is disadvantageous because it signifies the expenditure of a circulatory reserve and because it is associated with inefficiency in the need and utilization of oxygen

2 *Arteriolar Vasoconstriction* Arteriolar vasoconstriction occurs when there is a reduction in cardiac output Its compensatory effect is not to restore the cardiac output to normal but to redistribute the diminished output in such a manner as to maintain an adequate blood flow to vital areas Thus blood is diverted from the periphery and abdominal viscera to the brain and heart

Arteriolar vasoconstriction is an important compensatory mechanism in conditions which cause such a rapid and intense fall in cardiac output that actual restoration to normal is impossible The associated clinical picture is acute circulatory failure or shock (Chapter 12) But in chronic congestive failure in which the diminution in cardiac output is relatively moderate and occurs gradually arterial vasoconstriction and redistribution of blood are of minor importance for other mechanisms can be employed which are capable of restoring the cardiac output to adequate levels

Arteriolar vasoconstriction may serve not only to redistribute better the diminished cardiac output but also to initiate slower mechanisms which tend to restore an adequate output In particular the kidney undergoes arteriolar constriction whenever the cardiac output is diminished The resulting diminution in renal blood flow has been held responsible for the retention of sodium and water which helps to restore the cardiac output by increasing the blood volume and venous return In addition arteriolar vasoconstriction in various tissues results in a fall in capillary hydrostatic pressure which favors the absorption of interstitial fluid into the blood stream with a tendency to increase blood volume and cardiac output In cases of advanced heart failure in which the cardiac output falls significantly despite various compensatory mechanisms the blood pressure is usually maintained despite the fall in output This is possible only because of a compensatory increase in total peripheral resistance i e arteriolar constriction

The mechanism responsible for renal arteriolar constriction is uncertain It may be induced as part of a generalized splanchnic vasoconstriction which occurs when a diminished output inhibits the vasodepressor mechanism and the carotid sinus vagal arc Sympathetic stimulation has been regarded as excluded because the renal blood flow in congestive heart failure was not altered by a high spinal anesthesia[104] Humoral agents have also been invoked to account for renal arteriolar constriction in heart failure Renin has been demonstrated in the renal venous blood of patients with chronic congestive heart failure[10] Renal arteriolar constriction has also been attributed to the release of vasoexcitor material from the kidney due to renal hypoxia caused by an inadequate cardiac output[37]

3 *Increased Venous Return* The venous return over a period of time is equal to the cardiac output for the heart can only pump as much blood as it receives in a unit of time Factors increasing the venous return tend to increase the cardiac output The venous return may be augmented by (a) increasing the speed of the circulating blood or (b) increasing the circulating blood volume i e

the width of the stream returning at a given speed When the cardiac output falls or for some other reason is unequal to the demands of the tissues it may be made sufficient by compensatory mechanisms which increase the venous return either by accelerating the speed of the circulation or by augmenting the volume of the circulating blood

(a) *Increased Speed of Circulating Blood* During exercise or febrile states, the cardiac output is increased largely by acceleration of the speed of the circulation In certain pathologic states which render the ordinary output inadequate for body requirements, the abnormally high outputs required are attained largely by acceleration of circulating speed e g in cases of hyperthyroidism anemia, beriberi and arteriovenous fistula A diminution in peripheral resistance permits the more rapid circulation (p 186)

(b) *Increased Blood Volume* In most conditions leading to chronic congestive heart failure cardiac enlargement first develops and maintains an adequate output despite cardiovascular disturbances When this compensatory mechanism is no longer effective or when it is insufficient from the beginning restoration of cardiac output may follow an increase in the circulating blood volume In the heart lung preparation constriction of the aorta reduces the cardiac output but the output may be restored first by cardiac dilatation and when this is inadequate by an increase in the venous return to the heart In humans also an increase in blood volume by intravenous infusions augments the cardiac output

Similarly when the cardiac output falls because of failure of the heart, a progressive enhancement of the circulating blood volume tends to restore the cardiac output *Thus the blood volume may be represented as a fundamental homeostatic mechanism for maintaining an adequate cardiac output* The increased blood volume in congestive heart failure is due both to an increase in erythrocytes and to an enhanced plasma volume (p 220) The former may be the result of relatively inadequate blood flow to the bone marrow with an anoxic stimulus to erythrogenesis Increase in plasma volume is due essentially to abnormal renal retention of sodium and water

Eventually, these homeostatic compensatory mechanisms no longer maintain an adequate cardiac output This is due to the fact, noted by Starling[123] that there is a peak beyond which an increase in venous return does not further enhance the cardiac output (p 86) Progressive increase in the volume of circulating blood and of the venous return eventually overloads the failing heart Thereafter despite an augmented blood volume the cardiac output diminishes In part, at least failure of the increased venous return to be translated into greater cardiac filling and greater output is due to a pronounced rise in pressure within the cardiac chambers Although the venous pressure may be greatly elevated the venoatrial pressure difference which is the effective filling pressure, is diminished in this advanced stage of congestive heart failure[124]

In the late stages of congestive heart failure the cardiac output is low despite the body s efforts at compensation Arterial vasoconstriction and redistribution of the reduced output serve to maintain an adequate blood supply to vital organs Venous congestion and slowing of the blood stream are notable features The slowing permits a greater extraction of oxygen from each unit of blood (i e the arteriovenous oxygen difference is larger than normal) and this partly counterbalances the diminished blood flow Actual measurements with the aid of cardiovascular catheterization have shown an increased arteriovenous arterial oxygen not only in the general circulation but al o in the renal and hepatic circulations

The Relation of Increased Blood Volume to Venous Return and Venous Pressure

The retention of sodium and water over a period of time leads to an increase in the circulating plasma volume in patients with heart failure The greater blood volume is accommodated by an enlarged capacity of the venous system This augmentation of the blood volume denoting a wider stream of blood is translated into an increased venous return to the heart an effect similar to that of an intravenous infusion or transfusion

A clear distinction should be made between an increased venous return and an increased venous pressure The venous pressure is the resultant of two forces the venous return and the capacity of the receiving cardiac chamber to accept and eject that venous return A rise in venous pressure occurs when a cardiac chamber cannot handle its venous return

Rarely this occurs with a normal cardiac chamber if there is a sudden and enormous increase in the venous return; more commonly the venous pressure rises in the presence of a diseased or strained chamber with a venous return which is only moderately increased, e.g., by a rapid intravenous infusion.[2,107] Conversely, the reduction of an elevated venous pressure may occur either because the venous return is diminished (e.g., by phlebotomy, the application of tourniquets or by mercurial diuretics) or because the efficiency of the diseased heart is improved, e.g., by digitalis.

The cause of the elevated venous pressure in heart failure and its relation to the enlarged blood volume are disputed. According to the backward failure theory as delineated by Starling[138] the following sequence obtains:

Cardiac failure ⟶ elevated venous pressure and venous congestion ⟶ compensatory arteriolar constriction ⟶ anoxia of bone marrow ⟶ increased blood volume.

The hypervolemia, according to this concept, is secondary to the elevation in venous pressure. But it seems incredible that there can be more than a transient rise in venous pressure and venous congestion unless the blood volume is first increased. For as blood became impounded behind the failing chamber, the cardiac output and venous return would diminish and thus relieve the venous congestion and reduce the elevated venous pressure. Without sodium water retention by the kidney there is no increase in blood volume and without the latter there is no pulmonary or systemic venous congestion and no elevation in venous pressure. The elevated venous pressure cannot persist except by virtue of the augmentation of blood volume. This concept is supported by the experiments of Starr, Jeffers and Meade[140] who found no elevation of venous pressure following severe damage to the right ventricle, and by the observations of Starr[139] who found a persistent elevation of the venous pressure post mortem in patients who had died from congestive heart failure. The former experiments demonstrated that failure of a chamber per se may not cause an elevated venous pressure and the latter observations indicated that even when the factor of cardiac contraction is eliminated by death, the elevated venous pressure of chronic heart failure persists because of the augmented blood volume. Thus sodium water retention, increased blood volume and increased venous pressure are sequential integrated events in heart failure, not independent factors of varying importance. Furthermore, failure of the heart must mean an initial reduction in output as well as a damming of blood within and proximal to the failing chamber. Therefore anoxia of bone marrow or other tissues and organs could be as reasonably attributed to reduced cardiac output (forward failure) as to arteriolar constriction compensatory to elevated venous pressure (backward failure).

According to the forward failure theory the following sequence is postulated:

Cardiac failure ⟶ decreased renal blood flow ⟶ decreased renal excretion of sodium and water ⟶ increased extracellular fluid and increased blood volume.

Merrill[109] accepts this latter sequence of forward failure to account for the increased blood volume but invokes backward failure to account for elevated venous pressure behind the failing chamber. Warren and Stead[15] likewise accept the forward failure sequence leading to hypervolemia but attribute the elevated venous pressure first to venous vasoconstriction and second to increased blood volume. Clinical observations of engorged veins belie the existence of venoconstriction in congestive heart failure. This discrepancy has been explained by assuming increased venous tone in the deeper veins with consequent expulsion of blood into the more distensible superficial veins which appear engorged.[3] However, this concept in itself fails to explain why, if venoconstriction and hypervolemia are the causes of increased venous pressure, the venous pressure can be normal in the systemic circulation and elevated in the pulmonary system when the left side of the heart fails.

According to the mechanisms which I have outlined above, the sodium and water retention by way of the kidney occurs as a direct consequence of the initial reduction in cardiac output but not necessarily as a direct consequence of diminished blood flow to the kidney. Hypervolemia results from sodium water retention and maintains an elevation of venous pressure. Hypervolemia increases the venous return. *The venous pressure rises at the entrance to those chambers which are incompetent to receive and expel this augmented return.* Arteriolar vasoconstriction tends to develop

but it has no significant effect on the venous pressure in chronic heart failure Its chief purpose is to redistribute a diminished cardiac output in favor of the more vital organs, and perhaps to promote changes in renal function which result in increased blood volume (See also p 185 for effects of exercise)

Relation of Venous Return and Venous Pressure to Cardiac Output

There is no invariable relationship between *venous return and cardiac output* although as a rule an increase in the former enhances the latter But when a diseased chamber becomes overloaded a temporary further increase in the venous return may be followed by no increase or a reduction in the cardiac output *The relationship of venous pressure to cardiac output* is much more indirect If no other factors were operative an increased venous pressure would tend to elevate the cardiac output But changes in venous pressure are the result of other factors and these latter not the venous pressure control the output Thus in an overloaded failing heart reduction in the *venous return by phlebotomy may diminish* the venous pressure and increase the cardiac output by permitting the heart to function more efficiently But in the presence of a normal heart reduction of the venous return by hemorrhage is associated with an unchanged or diminished venous pressure and a reduction in cardiac output [8, 20] Similarly the venous pressure may not change during temporary closure and reopening of an arteriovenous fistula although the cardiac output is quite different in the two states because the healthy heart can handle the smaller or the larger venous return equally well

In summary the cardiac output increases as the venous return increases provided that the competence of the heart is normal or only moderately impaired With advanced myocardial incompetence, increased venous return may be followed by a reduction in cardiac output On the other hand the venous pressure may diminish, remain constant or increase as the cardiac output increases depending on the ratio of the venous return to the competence of the heart in handling the venous return

PATHOGENESIS OF LEFT SIDED AND RIGHT SIDED HEART FAILURE

In certain stages of coronary heart disease hypertension and rheumatic aortic and mitral valvular disease, the left chambers of the *heart fail while the right chambers are still* unimpaired The early reduction in left sided cardiac output or the initial elevation in pressure in the failing chambers and the pulmonary veins leads to a retention of sodium and water with its tendency to increase the circulating blood volume and restore the diminished cardiac output The normal right *chambers are competent to receive and eject* the venous inflow Right ventricular output now returns to the left chambers of the heart but the failing left chambers cannot competently accept and eject this venous return The disparity between inflow and capacity to put out blood leads to an increase in pulmonary venous pressure due to the increased *resistance of blood dammed up proximal to the* diseased chamber *The pulmonary venous pressure rises, not because of a 'backward pressure but because the increased venous return, moving in a forward direction, cannot be passed along with normal speed by the failing chamber* The augmented blood volume concentrated in the pulmonary vascular bed leads to the symptoms of left sided heart failure

In the earliest stages of isolated left-sided heart failure the increased blood volume tends to increase the pulmonary venous return to restore a normal left atrial and left ventricular output A normal right ventricular output is added to the residual in the pulmonary vascular bed and left cardiac chambers which was not ejected by the incompetent left chambers There is thus a constant engorgement of the pulmonary vascular bed which tends to stimulate the failing left heart to normal output But when these chambers become overloaded, the output may fall despite pronounced pulmonary congestion and increased pulmonary venous pressure Under such circumstances the blood flow is reduced because the rise in venous pressure does not keep pace with the increased resistance to blood flow at the site of the failing chamber

Right-sided heart failure may appear as an isolated syndrome due to pulmonary or pulmonary vascular disease or as a result of congenital cardiac disease or constrictive pericarditis More commonly right sided heart failure results from and is associated with left-sided heart failure In cases of intrinsic pulmonary or pulmonary vascular disease there is an increased resistance to blood flow in the pulmonary circulation, but compensa

tory dilatation and hypertrophy of the right ventricle maintain a normal cardiac output and consequently an elevated pulmonary arterial pressure. In left sided heart failure the increased resistance to right ventricular outflow is in the pulmonary veins and capillaries. Eventually the right ventricle fails and its residual volume and diastolic pressure increase. Right atrial and central venous pressure rise. Renal retention of sodium and water increases the blood volume and tends to increase the venous return and cardiac output. Now the failing right cardiac chambers are unable to accept and discharge the venous return and the systemic venous pressure rises. In constrictive pericarditis the venous pressure rises because the constricted ventricle cannot relax in diastole and accept the venous return normally. The engorgement of the systemic veins and their elevated venous pressure result in the clinical features of right sided heart failure.

Relation of Exercise to Pathogenesis of Symptoms of Heart Failure

The commonest first symptom of congestive heart failure is breathlessness on exertion. In the earliest stages there may be no symptoms at all unless the patient is engaging in exercise. This fact has been used to account for some of the apparently paradoxical findings in heart failure.

Thus the observation of normal cardiac outputs in some patients with heart failure is attributed by forward failure advocates to the fact that the determinations are made with the patient at rest when his cardiac output may in fact be normal. The presumption is that the output becomes inadequate during exercise at which time symptoms appear.[80] But since dyspnea occurs promptly it is necessary to explain how the inadequacy of output is so rapidly translated into symptoms. According to the forward failure theory this deficient output during exercise leads to a diminished renal plasma flow,[101] an increased tubular reabsorption of sodium[125] and a consequent salt water retention by the kidney. But it is implausible that this mechanism would produce an immediate augmentation of pulmonary congestion sufficient to induce clinical symptoms.

The adherents of backward failure explain the occurrence of dyspnea on exertion by the effects of exercise on the venous pressure.[66] The venous pressure is normal when the cardiac patient is at rest but increases as a result of back pressure during exercise. Such repeated transitory elevations of venous pressure are viewed as reducing the effective blood volume causing compensatory arteriolar constriction and in some way stimulating an eventual increase in blood volume. Or else the elevations of venous pressure increase renal venous pressure and cause renal retention of sodium and water. But this explanation likewise fails to explain the prompt development of dyspnea during exercise. Even though there may be an elevated systemic venous pressure during exercise[3] it does not explain how this could immediately increase the pulmonary congestion which is the basis of dyspnea (p 190)

The dyspnea which occurs promptly on exertion in patients with early left-sided heart failure can be explained according to the modified theory I have outlined. The left side of the heart has a limited reserve and a limited ability to handle an increased venous return. In early left sided heart failure a moderate pulmonary congestion exists even when the patient is at rest but the degree of congestion is below the threshold of causing clinical symptoms.

During exercise there is a prompt increase in the venous return. This increase is mediated entirely or almost entirely by an increased speed of circulation and not by any significant augmentation of circulating blood volume. The opening of vascular channels in the exercising muscle produces the equivalent of arteriovenous shunts which permit a speedier venous return to the heart. This mechanism of increasing the venous return unlike that of augmenting the blood volume is immediately significant.

According to principles already mentioned this increased venous return during exercise need have no effect on the systemic venous pressure if the right side of the heart is competent. But in reaching the low reserve left side of the heart it meets obstruction because of the inability of the incompetent left heart to receive and expel the enlarged return of blood. Pulmonary congestion occurs or if already present is increased and accounts for the prompt dyspnea. Because of the incompetence of the left side of the heart the initial increase in venous return under the stimulus of exercise may not be translated into an increased cardiac output. Hickam and Car

gill[69] found that in persons with left ventricular failure there is an elevated pulmonary arterial pressure which is further elevated during exercise but *there is little or no increase* in cardiac output

THE PATHOGENESIS OF HIGH OUTPUT HEART FAILURE

The pathogenesis of heart failure discussed above, refers to cases of primary heart disease in which heart failure is usually associated with some reduction in cardiac output Special features distinguish the development of heart failure in such conditions as hyperthyroidism anemia, beriberi, arteriovenous fistula osteitis deformans and severe pulmonary emphysema in which the cardiac output is elevated (See also discussion under individual diseases)

These conditions are all characterized by an increased tissue need for blood which can be compensated by an augmented cardiac output In patients with anemia and severe emphysema the increased need is due to the deficient oxygen content of the blood in those with hyperthyroidism it is due to increased metabolic requirements in those with arteriovenous fistula the need arises because short circuiting of blood deprives a large area of an adequate blood supply in those with beriberi a deficient content of thiamine is the apparent cause In cases of osteitis deformans the mechanism is that of arteriovenous fistula[35] The required compensatory increase in cardiac output is effected by an increased venous return The latter occurs only in part through an increased blood plasma volume and chiefly through an increased speed of the circulation The latter is made possible by a decrease in the peripheral resistance

In cases of heart failure due to cardiac or valvular disease the initial fall in cardiac output leads to peripheral vasoconstriction and increased peripheral resistance which inhibit speeding of the circulation Restoration of an adequate cardiac output can only be accomplished by augmentation of the blood volume In the high-output groups of cases the initiating disturbance begins in the periphery, not the heart and results in a diminished peripheral resistance which favors speeding of the circulation The diminished peripheral resistance may be due to the presence of a shunt (arteriovenous fistula) or to vasodilatation caused by hypermetabolism anemia and the like The quickened speed of circulation increases the venous return and *the cardiac output to the required level* In most of these conditions there is also some utilization of the compensatory effect of an increased plasma volume depending on the extent to which speed alone can satisfy the excessive demand for blood Thus an increased plasma volume appears to be stimulated when the compensatory increase in speed does not adequately elevate the cardiac output The need for this additional compensation may arise because the acceleration of the circulation diminishes the oxygen utilization per unit of blood flow

Heart failure occurs when the heart despite its enlarged output is no longer satisfying the exorbitant demands of the *tissues for blood When this happens* the same mechanisms described in the low output cases lead to sodium and water retention hypervolemia and increased venous return in an effort to attain the necessary output Increased splanchnic arteriolar constriction occurs but is usually insufficient to neutralize the diminished total peripheral resistance Eventually as above, the failing heart is unable to handle the increased venous return or to respond with an increased cardiac output At this point the cardiac output falls from its peak, but despite heart failure the output is still considerably in excess of the usual normal Plasma hypervolemia becomes associated with the increased speed of circulation In the low output cases hypervolemia is associated with retarded circulatory speed

Chapter 9

THE PATHOGENESIS OF INDIVIDUAL MANIFESTATIONS OF CONGESTIVE HEART FAILURE

PATHOGENESIS OF CARDIAC DYSPNEA

Dyspnea has been defined as subjective distress associated with difficulty in breathing (p 142) The following discussion concerns not only the mechanisms responsible for the objective abnormalities in pulmonary respiration but also the cause of the accompanying subjective discomfort

The occurrence of dyspnea in heart failure has been related to three possible mechanisms

(1) *An inadequate cardiac output and blood flow to the respiratory center stimulates increased respiratory effort*

(2) *An accumulation of carbon dioxide, a reduction in oxygen or a diminution in the pH of the blood* produces dyspnea by stimulating the respiratory center and/or carotid sinus,

(3) *Pulmonary congestion causes rigidity of the lung* and impairs normal reflex breathing because of mechanical interference with pulmonary expansion and retraction

CEREBRAL BLOOD FLOW AND DYSPNEA

Dyspnea has been attributed to an inadequate cardiac output and consequent ischemia of the respiratory center [40] But dyspnea is an *early* symptom of left heart failure and in early heart failure the cardiac output is usually normal The cardiac output falls as heart failure advances Yet dyspnea may be alleviated when progressive heart failure affects the right as well as the left cardiac chambers In cases of acute circulatory failure (shock) there is a pronounced diminution in cardiac output with minimal or no dyspnea Comparative studies of the oxygen content of arterial and internal jugular blood in patients with cardiac dyspnea showed no increase in arteriovenous oxygen difference, as would be anticipated if there were slowing or insufficiency of the cerebral blood flow [3] Other observers have found the cerebral arteriovenous oxygen difference to be increased in most cases of heart failure Determinations of the cerebral blood flow by the nitrous oxide method indicated a reduction proportional to the diminution in cardiac output according to Scheinberg[105] and Moyer et al,[84] but cerebral oxygen consumption was virtually normal On the other hand, Novack et al [89] found the cerebral blood flow to be normal in congestive heart failure, as did Moyer et al [87] and demonstrated that the reductions previously reported were probably due to associated cerebral atherosclerosis Thus the occurrence of dyspnea in heart failure cannot be correlated with a reduction either in cardiac output or in the blood flow to the respiratory center

BLOOD CHEMICAL CHANGES AND DYSPNEA

Numerous observations indicate that chemical changes in the blood which might result from heart failure are not primarily responsible for cardiac dyspnea although they may contribute to its occurrence or increase its severity in advanced stages of heart failure The oxygen and carbon dioxide content and the pH of the blood are the pertinent factors Only the composition of *arterial* blood, which supplies the respiratory center and carotid body is significant But changes in venous blood could conceivably influence peripheral respiratory chemoreceptors reported to be present in the pulmonary arteries[109] or lungs [■] reports not, however supported by the more recent studies of Aviado et al [5]

Arterial Oxygen

Normally the arterial oxygen saturation is 95 to 99 per cent. Meakins and his co-workers[84] and Frazer and co-workers[41] observed *normal oxygen saturations in almost* all cases of cardiac dyspnea unless the heart failure was very severe or there were pulmonary complications. Cullen and co-workers[2] discovered no arterial anoxemia even after exercise in patients with slight or moderate heart failure associated with dyspnea. Although the arterial oxygen saturation is usually normal, it is slightly reduced to concentrations of 90 to 95 per cent in many cases.[85] *Because of the character of the* oxyhemoglobin dissociation curve in this concentration range, the arterial oxygen tension is significantly diminished even with slight reductions in oxygen saturation.[17] Nevertheless it is more relevant that in the majority of cases of heart failure dyspnea occurs when the arterial oxygen saturation and oxygen tension are normal.

These observations reveal that the common *form of cardiac dyspnea, which appears early* in the course of left-sided heart failure, is not due to a reduction in the arterial oxygen saturation or content. Furthermore low arterial oxygen contents in certain cases of congenital heart disease with cyanosis are frequently unaccompanied by dyspnea. Of course there are instances of heart failure with pulmonary complications or of congenital heart disease with cyanosis in which a very low arterial oxygen content is a contributing or major factor in dyspnea. But this is the exceptional, not the usual, pathogenesis of cardiac dyspnea.

Tissue anoxia may be present in heart failure, especially after exercise, even when arterial oxygen is normal. The presence of tissue anoxia is supported by the finding of a low venous blood oxygen tension. It would appear that this could contribute to dyspnea only if it affected pulmonary arterial or other unproven venous respiratory chemoreceptors. But venous hypoxemia denotes also tissue anoxia of the respiratory centers and this might increase the respiratory stimulus.

Arterial Carbon Dioxide

Similarly cardiac dyspnea cannot be attributed to an increase in arterial carbon dioxide. The concentration and tension of carbon dioxide in the arterial blood is actually reduced and not elevated.[40] The reduction is a secondary effect of the hyperventilation associated with dyspnea. Only occasionally, with extreme pulmonary congestion and edema or with severe pulmonary emphysema or other *extensive pulmonary complications, is there* an interference with carbon dioxide elimination and a consequent elevation of its concentration in the blood. In such instances it may contribute to hyperventilation and associated dyspnea. A reduction in arterial carbon dioxide tends to increase cerebral vascular resistance, but no significant reduction in cerebral blood flow has been found to result from altered arterial carbon dioxide in heart failure.[39]

Hydrogen Ion Concentration

The hydrogen ion concentration of the blood is either normal or slightly diminished (gaseous alkalosis) in cases of cardiac dyspnea due to pure left-sided failure.[4] Therefore arterial acidemia cannot be held accountable for this type of dyspnea. On the other hand when heart failure is associated with carbon dioxide retention due to extensive pulmonary disease, the hydrogen ion concentration in arterial blood increases (gaseous acidosis). A reduction in the pH of the blood may also result from the accumulation of fixed acids such as lactic and pyruvic acid in very advanced or terminal cases of heart failure with pronounced peripheral stasis or in cases of heart failure with renal insufficiency.[40] During exercise also patients in heart failure accumulate fixed acids more readily than normally.[, 85] I have seen a marked reduction in hydrogen ion concentration with clinical acidosis in patients in heart failure treated continuously with ammonium chloride. Under these special circumstances arterial acidemia may produce dyspnea by excessive stimulation of the carotid body and respiratory center. However, the dyspnea of acidemia resembles the deep Kussmaul type of hyperventilation seen in diabetic acidosis rather than the usual shallow breathing characteristic of cardiac dyspnea.

PULMONARY CONGESTION AND RIGIDITY AS THE CAUSE OF CARDIAC DYSPNEA

The weight of evidence supports the belief that cardiac dyspnea is due, as a rule, to pulmonary congestion resulting from left-sided heart failure, although measurements of the pulmonary blood volume are equivocal.[13, 11, 8, 11] From the clinical pathologic

viewpoint this concept is supported by the observation that dyspnea is the essential symptom of left sided heart failure and that pulmonary congestion is the essential pathologic feature The pulmonary rigidity may be due to increased pulmonary capillary and venous pressure and interstitial edema as well as possible encroachment of congested pulmonary capillaries on the alveolar spaces

Pulmonary congestion disturbs respiration either (a) by hampering the diffusion of oxygen and thus impairing aeration of the blood or (b) by interfering mechanically with the expansion and retraction of the lungs We have seen that chemical changes in the blood do not appear to account for the usual cardiac dyspnea and therefore any tendency to impairment in aeration is well compensated It remains to discover by what means mechanical disturbances in pulmonary expansion and retraction account for most instances of cardiac dyspnea

The Hering Breuer Reflex

Normal involuntary respiration is dependent on the Hering Breuer reflex in which the changing alveolar tension is the stimulus the vagus nerve is the afferent arc to the respiratory center and the intercostal and phrenic nerves are the efferent pathways to the intercostal and other muscles of respiration including the diaphragm A diminished alveolar tension results in muscular expansion of the chest wall and diaphragm followed by pulmonary expansion due to the increasing negative pleural pressure The high intra alveolar tension at the peak of inspiration causes reflex relaxation of the chest wall and the intrinsic elasticity of the lung causes pulmonary retraction

Pulmonary Congestion and Reflex Stimulation of Respiration

Experimental evidence supports the theory that pulmonary congestion stimulates respiration by way of the Hering Breuer reflex and thus causes the rapid shallow breathing of cardiac dyspnea The production of pulmonary congestion in cats[1] and dogs[47] by pulmonary vein ligation and infusion of blood into the pulmonary artery or by multiple pulmonary embolization[3] [9] caused rapid shallow breathing which disappeared after section of the vagi The altered respiration was unassociated with changes in the chemical composition of the blood If the stimulus to rapid breathing is regarded as distention of the pulmonary alveoli the reflex is termed the Hering Breuer reflex if the stimulus is distention of the pulmonary vessels the reflex is termed the Churchill Cope reflex[11]

Pulmonary Congestion and the Rapid Shallow Respiration of Cardiac Dyspnea

To understand the manner in which pulmonary congestion induces the rapid shallow respiration of cardiac dyspnea it should be recalled (1) that distensibility of the lungs is essential to their easy expansion during inspiration and their elasticity is essential to their retraction during expiration and (2) that the lung like erectile tissue becomes rigid and inelastic when congested with blood[29 30 11] Because of the rigidity of the lungs the normal increase in alveolar tension during inspiration causes relatively less expansion of the alveoli for the same reason there is relatively less retraction during expiration than normally Thus the end points of pulmonary inflation and deflation are brought close together with a consequent shallow respiration

Were there no compensations the shallow respiration would be accompanied by inadequate pulmonary aeration and a resulting accumulation of carbon dioxide and deficiency of oxygen in the blood Since the volume of pulmonary ventilation can be modified only by alteration in respiratory amplitude or in respiratory rate it is apparent that the reduction in respiratory amplitude in congestive heart failure can be neutralized only by a compensatory increase in rate i e by tachypnea Thus compensatory tachypnea accounts for our observation that despite the shallow respiratory excursions of the inelastic congested lung homeostasis of the blood with respect to its oxygen content is long maintained in congestive heart failure

Pathogenesis of Tachypnea in Heart Failure

The exact mechanism by which pulmonary congestion induces tachypnea is uncertain It seems clear that the first consequence of pulmonary congestion and rigidity is a deficiency in ventilation due to (a) a diminution in the quantity of air inspired and exhaled with each breath (b) uneven ventilation because less favorably situated alveoli and those which are most rigid are not expanded at all and (c) impairment of diffusion because of the thickened alveolar septa encroachment of ectatic wide capillaries on the alveolar spaces and transudation of fluid into the alveoli

Initially, these disturbances tend to cause a reduction in oxygen content of the blood The carotid body and respiratory center are chemically stimulated and induce increased respiration Since pulmonary rigidity prevents or limits augmentation in the depth of respiration ventilation is enhanced by an increase in the rate The degree of acceleration and the amount of increase in ventilation appear to be that which suffices to restore the normal oxygen content of the blood

Vagal reflexes from the congested, rigid lung are concerned in the production of compensatory tachypnea, for in experimental pulmonary congestion rapid breathing no longer is induced if the vagi are cut Increased sensitivity of the sensory endings concerned with the Hering Breuer reflex and more frequent stimulation to inspiration and expiration because of the shallow respiratory range may account for the resulting tachypnea Reflex tachypnea has also been attributed to increased pressure in the pulmonary veins and left atrium on the basis of experimental observations [5]

If there were a change only in the *quantity* of each breath during shallow respiration of heart failure then a 30 per cent reduction in amplitude would require a 30 per cent increase in rate to compensate The total amount of ventilation would be unaltered However pulmonary rigidity causes not only a reduction in ventilation but an inefficiency in ventilation and in diffusion aeration of the blood Consequently in the example mentioned a 30 per cent reduction in amplitude might require a 50 per cent compensatory increase in respiratory rate The total quantity *of ventilation per minute is increased*[81] but the effective aeration of the blood is normal Since carbon dioxide diffuses more readily than oxygen the hyperventilation needed to restore the normal oxygen saturation results in an excessive elimination of carbon dioxide

In summary pulmonary congestion causes pulmonary rigidity which restrains inspiration and expiration and results in restricted or shallow breathing An increased respiratory stimulus most probably neurogenic by way of an exaggerated Hering Breuer reflex but also or occasionally chemical (hypoxemia), increases ventilation by increasing the rate and to a limited degree the depth of respiration

Relation of Cardiac Dyspnea to Pulmonary Ventilation and Vital Capacity

It has been mentioned that the shallow rapid respirations of congestive heart failure are associated with an elevated total ventilation [81] Peabody and his associates[94] also demonstrated that the vital capacity is reduced and that there is a close correlation between the degree of reduction and the severity of dyspnea Frank et al [38] discovered a symmetrical reduction in both inspiratory capacity and expiratory reserve, the elements that compose the vital capacity (p 972) Christie and Meakins[20] showed that in patients with congestive heart failure the vital capacity was a gauge of the rigidity of the lungs More recent observations have demonstrated only fair correlations between dyspnea and vital capacity [1, 2, illegible]

The intensity of dyspnea has been correlated not only with the reduction in vital capacity but also with the increase in rate and total ventilation Harrison and his co-workers[49] observed that dyspnea usually occurred when the ratio $\frac{\text{ventilation}}{\text{vital capacity}}$ exceeded a given value More recently an excellent correlation has been found between the occurrence of dyspnea and the ratio of breathing reserve to maximal breathing capacity (p 974) The latter averages 100 liters per minute for normal females and 150 liters per minute for normal males and is determined by having the patient breathe in and out as fast and deeply as possible for 5 to 20 seconds (p 974) The breathing reserve is the maximal capacity minus the actual ordinary minute ventilation in any given state In congestive *heart failure there is both a reduction in* maximal breathing capacity and an increase in actual ventilation, the breathing reserve is diminished by both of these changes Dyspnea has usually been found to occur when the breathing reserve is below 70 or 65 per cent of the maximal breathing capacity

Richards et al [10] found a slight decrease in the expiratory reserve volume and a slight increase in the residual volume and functional residual volume with moderate congestive heart failure In severe heart failure there was a sharp reduction in the residual volume and functional residual volume

This correlation between the severity of dyspnea and quantitative changes in ventilatory function does not denote that the dyspnea

is caused by these changes The increased respiratory rate and diminution in vital capacity and maximal breathing capacity are *consequences* of pulmonary congestion and rigidity just as is the dyspnea These and other quantitative changes in pulmonary respiration are merely indices of the pulmonary rigidity It is the pulmonary congestion and rigidity per se which cause dyspnea This is confirmed by recent pressure flow studies with an intra-esophageal balloon, which revealed an alteration in the mechanics of ventilation caused by changes in the elastic properties of the lung [19, 21]

PATHOGENESIS OF SUBJECTIVE DISTRESS DURING DYSPNEA

The mechanisms discussed above attempt to explain the pathogenesis of the rapid shallow breathing and the objective disturbances in ventilation associated with dyspnea but do not reveal why the patient suffers distress The most probable causes for subjective discomfort are the excessive work of the muscles of respiration and the use of muscles not ordinarily required in unconscious breathing to distend and deflate the rigid lungs The increased intrathoracic pressure resulting from the loss of pulmonary elasticity[20] and the increase in the number of respirations per unit time add to the burden Pulmonary ventilation is limited by the maximal work capacity of the respiratory muscles When the latter cannot readily provide the increased ventilation in heart failure needed to aerate the blood dyspnea results [101] See also Work of Breathing and Respiratory Effort[77, 78] (p 975) The localization of the distress in the upper abdomen, chest wall and neck seems to confirm the impression that the subjective discomfort with dyspnea arises from fatigue of the muscles of the chest wall and of the diaphragm The exaggerated work of the respiratory muscles accounts for most of the increased oxygen consumption in dyspneic patients Various constitutional and psychic conscious and subconscious factors influence the character and degree of discomfort (dyspnea) resulting from this exaggerated work and fatigue of the respiratory muscles

PRODUCTION OF DYSPNEA DURING RIGHT SIDED HEART FAILURE

Dyspnea is usually present in patients with right sided heart failure As a rule it is due to persistence of the pulmonary congestion of left-sided heart failure, since the latter usually precedes right sided heart failure But following failure of the right ventricle the dyspnea may be partially alleviated in proportion to the relief of pulmonary congestion

In some cases right-sided heart failure is secondary to primary pulmonary disease such as extensive emphysema, fibrosis, etc The dyspnea may then be caused entirely by the pulmonary disease and not by failure of the right side of the heart

In addition to the contributions of pre existing pulmonary congestion or of intrinsic pulmonary disease to the production of dyspnea in patients with right heart failure, the latter itself may contribute as follows

1 Severe peripheral venous stasis may cause a significant reduction in the oxygen tension and an increase in the carbon dioxide tension of the venous blood returning to the lungs The combination of pulmonary congestion and severe tissue stasis cannot be adequately compensated and the oxygen saturation of the arterial blood is significantly reduced The resultant hypoxia of the carotid body and respiratory center may contribute to the occurrence of dyspnea

2 Severe venous stasis with right sided heart failure may lead to an increase of lactic acid in the blood This may increase the hydrogen ion concentration of the blood especially in hypertensive patients with renal damage The change in chemical composition of the blood stimulates the respiratory center and may cause hyperventilation and dyspnea

3 Right sided heart failure is associated with a rise of pressure in the venae cavae and right atrium Harrison and his associates[11] found that when they elevated the pressure in the venae cavae by the rapid injection of fluid or by insertion and inflation of a balloon there was an increase in respiration which did not occur if the vagi were sectioned These experiments suggest that an elevation of pressure in the venae cavae and right atrium, such as occurs with right sided heart failure may reflexly stimulate breathing and therefore may contribute to the development of dyspnea However, the occurrence of such reflexes in human beings is questionable

4 Hydrothorax ascites and extreme and sudden hepatic enlargement occurring during right-sided heart failure may precipitate or

accentuate dyspnea, by interfering with the distensibility of the lungs[102]

RELATION OF EFFORT TO CARDIAC DYSPNEA

In its early stages cardiac dyspnea is usually initiated only after certain degrees of exertion which however, did not cause dyspnea before the patient's heart failed Pulmonary congestion with consequent rigidity *of the lungs is the fundamental basis* for cardiac dyspnea whether it appears during rest or after exercise The patient with left sided heart failure experiences pulmonary congestion, even at rest, but it may be insufficient to produce dyspnea During exercise this congestion is further increased until the patient experiences dyspnea Thus very severe pulmonary congestion may cause dyspnea at rest, with lesser degrees of congestion dyspnea only occurs when pulmonary congestion is intensified to the symptom level by exercise or other means

Exercise increases pulmonary congestion by augmenting the venous return[71] If the right heart is competent this augmented return is effectively expelled into the already congested lung while the weak left heart is unable to drain effectively the pulmonary venous return For this reason pulmonary congestion and dyspnea are usually most intense when failure is limited to the left heart In patients with left-sided failure due to mitral stenosis exercise *resulted in a rise in pulmonary capillary* pressure and a reduction in pulmonary compliance[103] If the increased congestion is associated with a high enough pulmonary capillary pressure pulmonary edema occurs and intensifies the dyspnea Psychic stimulation of respiration, increased production of lactic acid reflexes from the muscles[**] and reflexes stimulated by an increase in venous pressure have also been suggested as factors in the dyspnea induced by exercise[43]

PATHOGENESIS OF ORTHOPNEA

Since essentially the same factors are concerned in the pathogenesis of orthopnea as of any other form of dyspnea we will consider only the role of the recumbent position in the promotion of dyspnea Again it must be emphasized that, like dyspnea cardiac orthopnea is a cardinal symptom of left sided heart failure and is due fundamentally to pulmonary congestion Furthermore when the right side of the heart fails and pulmonary congestion is relieved orthopnea is often alleviated despite the elevation of venous pressure peripheral tissue stasis and other related phenomena

1 Increased Pulmonary Congestion in Recumbent Position

There is considerable evidence that there is a shift of blood from the upper half of the body to the splanchnic area and lower extremities with assumption of the erect position and the reverse with recumbency[33] This gravitational shift of blood is noted clinically in the altered degree of filling of the superficial veins of the extremities and was demonstrated plethysmographically by Atzler and Herbst[6] The circulating blood volume is increased in the recumbent position[1, 4, 95] It may be presumed that in the recumbent position the shift of blood to the thorax from the lower extremities and splanchnic viscera increases pulmonary congestion Most significant are the observations that the cardiac output and therefore the venous return are augmented when an individual changes from an upright to a recumbent position[83] In the presence of left-sided failure such an increase in venous return intensifies pulmonary congestion as explained under the effect of exercise

Confirmation of increased pulmonary congestion in the recumbent position is offered by comparative measurements of vital capacity *when patients with orthopnea are* erect and supine Christie and Beams[19] found that while the vital capacity in normal persons was diminished 5 per cent by a shift to the horizontal position there was an average fall of 25 per cent in patients with orthopnea This observation has been confirmed by others including Calhoun and his co-workers[17] Since the diminution in vital capacity is a measure of the degree of pulmonary congestion and rigidity of the lung these changes in vital capacity indicate an increase in pulmonary congestion with assumption of a horizontal position More recently Marshall et al[77] determined that in patients with orthopnea due to mitral stenosis and left-sided heart failure there was an increase in elastic resistance (diminished compliance) on lying flat and a marked increase in respiratory work This was associated with diminished tidal volume increased respiratory rate and dyspnea Adoption of the recumbent position by increasing the pulmon

ary congestion and rigidity already present in patients with heart failure either initiates or intensifies dyspnea by mechanisms already discussed

2 Mechanical Interference with Pulmonary Ventilation in Recumbent Position

When the patient with cardiac orthopnea reclines the diaphragm is elevated and consequently interferes with thoracic breathing by shortening the thoracic compartment available for expansion[8] The mechanical factor is especially important in the presence of cardiac ascites enlarged liver and abdominal tympanites which not only elevate the diaphragm but also interfere with diaphragmatic breathing Even in normal subjects changing from the upright to the recumbent position diminishes the expiratory reserve (p 972) probably due to elevation of the diaphragm[10]

PATHOGENESIS OF PAROXYSMAL DYSPNEA AND CARDIAC ASTHMA

Relation to Pulmonary Congestion[72]

This discussion is concerned with the paroxysmal attacks of dyspnea which as a rule occur at night and wake the patient from sleep As indicated by Hope[11] who first employed the term cardiac asthma pulmonary congestion is the fundamental basis of these attacks as it is for dyspnea at rest or on exertion That cardiac asthma results from pulmonary congestion is indicated by its occurrence almost exclusively in patients with hypertensive aortic or mitral valvular or coronary artery disease or other conditions which are complicated by left sided heart failure Circulatory studies on patients between attacks of cardiac asthma also show that they are suffering from pulmonary congestion Weiss and Robb[1 8] found that there was an increase in the volume of blood in the lungs a retardation of the pulmonary blood flow and a reduction in vital capacity On the other hand the systemic circulation is unchanged since the stroke and minute volume the velocity of peripheral blood flow the arteriovenous difference and the systemic venous pressure are all normal in the great majority of cases Furthermore the observations of Weiss and Robb[1 6] and of Calhoun et al[17] have shown that neither a diminished blood flow to the respiratory center nor changes in blood gases can account for cardiac asthma

Clinical and circulatory observations reveal that *during* the attacks of cardiac asthma the severity of pulmonary congestion is increased Pulmonary râles appear or become more extensive The second pulmonic sound becomes more accentuated and may be louder than the second aortic sound even when hypertension is present The low vital capacity is further diminished during the attacks The velocity of blood flow in the lungs is diminished and there is an increase in the volume of the pulmonary vascular bed indicating an intensification of pulmonary engorgement[1 6]

The actual precipitation of an attack of cardiac asthma is due to some factor or factors which intensify the preexisting pulmonary congestion sufficiently to cause clinical dyspnea Such factors usually intensify pulmonary congestion by enhancing the venous return[11] In addition variations in the sensitivity of the respiratory center e g during sleep are also concerned both in the initiation and subsidence of an attack of cardiac asthma

Mechanism of Precipitating Factors in Paroxysmal Dyspnea or Cardiac Asthma

Recumbency Often the patient suffers from orthopnea while awake and therefore goes to sleep while propped up on pillows The attack of dyspnea is precipitated when he slides down during sleep to a more horizontal position The significance of this factor is confirmed by the frequency and rapidity with which an attack is relieved as soon as the patient sits up or gets out of bed to go to a window The mechanisms involved were discussed under orthopnea The main factor is a redistribution of blood which increases the return to the right side of the heart and lungs

Sleep A characteristic feature of cardiac asthma is its occurrence after patients fall asleep It has been assumed that the diminished irritability of the central nervous system when the patient is asleep permits the lungs to become much more engorged as a result of recumbency than when he is awake When the patient is awake reflex hyperventilation and slight dyspnea appear before pulmonary congestion is intense and the patient consciously or unconsciously assumes a somewhat oblique if not completely vertical position During sleep however the degree of congestion may become so great as to be associated with bronchial spasm edema and

transudation into the alveolar spaces Then the resumption of the erect position may not be adequate to stop the attack immediately An increase in pulmonary blood flow, noted during sleep, may also increase pulmonary congestion [46]

Cough In my experience cough is usually manifested after the attack has already begun and is not a precipitating factor

Terrifying dreams during sleep have been said to precipitate an attack, perhaps by causing an elevation in blood pressure This factor cannot be evaluated Furthermore nightmares occur frequently in cardiac patients who do not experience nocturnal dyspnea

Diminished Muscular Activity Christie[18] has suggested that diminution of muscular activity during sleep causes venous stagnation within the muscles The attacks may then be precipitated by *sudden muscular movement* with a consequent increase in venous return

Increased Blood Volume An increased blood volume due to the resorption of latent edema from the dependent portions of the body when the patient becomes recumbent at night may be an important cause of paroxysmal dyspnea according to Brunn[15] and others [95] This would have the effect of increasing the venous return and thereby the degree of pulmonary congestion The fact that the attacks may be diminished or prevented by a low sodium intake and vigorous diuresis supports the belief that an augmented blood volume is important in the underlying pulmonary congestion

Cardiac asthma is a term applied to those attacks of nocturnal dyspnea which are characterized by wheezing respirations and audible rhonchi in the chest

The exact mechanism responsible for the wheezing resembling that of bronchial asthma, is uncertain but bronchial obstruction is presumed to be the cause This may be due to congestion and edema of the bronchial mucosa, to actual edema fluid in the bronchial lumen or to bronchoconstriction [97] It is uncertain whether this asthmatic dyspnea is due to vagal reflexes from the congested lung to the affected bronchi,[illegible] to congestion and increased hydrostatic pressure in the bronchial capillaries or whether it appears when intense pulmonary congestion occurs in predisposed allergic persons [114]

PATHOGENESIS OF ACUTE PULMONARY EDEMA

Attacks of acute pulmonary edema are essentially severe episodes of paroxysmal dyspnea which are due to the same fundamental factor of sudden intensification of the pulmonary congestion of left sided heart failure This concept is supported by the frequent occurrence of pulmonary edema in the same patients as suffer from cardiac asthma its development under similar circumstances (except that it occurs at any time of the day and not necessarily after retiring), and the common transition of an attack of cardiac asthma into one of pulmonary edema

The essential feature of acute pulmonary edema is the rapid transudation of fluid out of the pulmonary capillaries into the alveoli, beyond the capacity of the pulmonary lymphatics to resorb this fluid [illegible] Elevation of pulmonary capillary hydrostatic pressure and increased capillary permeability are the major factors responsible for pulmonary edema, but reduction in plasma proteins or impairment of function or elevation of pressure in the lymphatics may be contributory [illegible, 90, illegible] Sodium and water retention are important insofar as they contribute to or maintain the elevated pulmonary venocapillary pressure In congestive heart failure acute elevation of the pulmonary capillary pressure appears to be the major causative factor It is probable that a critical level of about 35 to 40 mm of water must be exceeded i e, above the plasma oncotic pressure [illegible, 70] Capillary permeability if altered at all tends to be diminished owing to fibrosis and thickening of the capillary basement membrane and alveolar capillary membrane as in mitral stenosis Such impairment of permeability may account for imperfect correlations between the height of the pulmonary capillary pressure and the presence or absence of pulmonary edema [4] Acute pulmonary edema occurs in those cardiac diseases which are complicated by left ventricular or left atrial failure in which there is a continuous pulmonary congestion and elevation of pulmonary capillary pressure The actual onset of acute pulmonary edema is triggered by a marked increase in resistance to outflow from the left cardiac chambers a sudden reduction in left ventricular or left atrial output an excessive rapid increase in venous return and

right ventricular output or a combination of these, which swiftly raise further the elevated pulmonary capillary pressure above the critical edema level

The precipitation of pulmonary edema by intravenous infusions of saline or plasma or by transfusions of blood and its occurrence in mitral stenosis after strenuous exertion, during pregnancy or post partum or after excessive sodium intake, supports the theory that pulmonary edema like cardiac asthma may be elicited by a sudden augmentation of the venous return and intensification of pulmonary congestion and capillary hypertension Conversely acute pulmonary edema is often relieved by venesection or the application of tourniquets to the extremities—factors which reduce the venous return and the pulmonary capillary pressure Experimentally Welch[121] long ago demonstrated in rabbits that pulmonary edema could be produced by compression of the left ventricle or aorta and by ligation of most of the pulmonary veins procedures which diminished the left ventricular output and caused intense pulmonary congestion and elevation of pulmonary capillary pressure Attacks of pulmonary edema in hypertensive patients are precipitated by sudden increases in blood pressure (i e in peripheral resistance)[54] at the same time that resorption of edema fluid increases the venous return when such patients have been recumbent during the night Marked elevation of pulmonary capillary pressure and pulmonary edema occur in acute myocardial infarction as a result of severe left ventricular damage and diminished output In mitral stenosis further elevation of pulmonary capillary pressure and pulmonary edema may occur when the tachycardia exercise or other factors increase the cardiac output[44] (p 654) Because of the unyielding resistance of the narrow mitral orifice the increased blood flow is translated into increased pulmonary venous and capillary pressure There is evidence that acute pulmonary edema occurs not as a rule in the most advanced cases of mitral stenosis but in moderately severe cases in which the cardiac output can be increased with exercise[34, 45, 1.5]

The chief difference between pulmonary edema and cardiac asthma is the occurrence in the former of a much more extensive exudation of edema fluid around the alveolar septal vessels within the alveoli, in the bronchial walls and in their lumina The edema results from a pronounced increase of the hydrostatic pressure in the pulmonary capillaries due to the intensification of pulmonary venous engorgement The relatively high protein content (2 to 4 per cent) in pulmonary edema fluid suggests that increased permeability of the vessel walls facilitates the formation of pulmonary edema, according to Drinker[27]

Other Theories of Pulmonary Edema[74, 2]

Pulmonary edema is not invariably due to left-sided heart failure It may occur (a) in pneumonia and in poisoning with certain war gases (phosgene) and especially (b) in certain diseases of the brain such as trauma, tumors, hemorrhage and encephalitis In the former group local damage to pulmonary capillaries may predispose to edema by increasing capillary permeability, its occurrence in the latter suggests a neurogenic mechanism which could likewise promote permeability But Paine and associates[92] found that even in the group of patients with serious disease of the central nervous system in whom pulmonary edema developed the majority showed evidence of heart disease at autopsy or had hypertension during life Neurologic disease may induce pulmonary edema not by increasing capillary permeability but by adding the stress of neurogenic hypertension, anoxia and cardiac arrhythmia to underlying cardiac disease

The pulmonary edema of clinical left ventricular or left atrial failure has also been attributed to neurogenic reflexes arising in the root of the aorta, the carotid receptors the pulmonary artery and large veins and in the left ventricle[119, 74] Wassermann[119] described observations on patients whose attacks of paroxysmal dyspnea were relieved by section of the depressor nerves and by pressure over the carotid sinus

There is convincing evidence favoring sudden intensification and critical elevation of pulmonary capillary pressure as the fundamental cause of the pulmonary edema in clinical cases of left sided heart failure The efficacy of a reduction in blood volume and venous return by sodium restriction mercurial diuresis venesection or the application of tourniquets in preventing and controlling pulmonary edema has been mentioned However, the prompt therapeutic effectiveness of morphine in many cases is noteworthy and

suggests some causative role of the nervous system in the production of cardiac asthma and pulmonary edema But special aortic carotid, ventricular or other vascular reflexes need not be postulated The theory of pulmonary congestion as the basis of pulmonary edema has necessarily included the sensitivity of the respiratory center in mediating the efferent neural arc which effects increased respiratory rate and ventilation Since the compensatory tachypnea must be mediated through the respiratory center, morphine provides relief by depressing the sensitivity of this center to the stimuli which induce increased respiratory ventilation The frequently marked and rapid relief of cardiac asthma or pulmonary edema by morphine is largely due to its diminution of the work of respiration by reducing the quantity of ventilation Anxiety also is allayed There is no direct evidence that it corrects the basic cause or mechanisms of pulmonary edema

The pathogenesis of acute pulmonary edema occurring in conditions other than left heart failure may be unrelated to pulmonary congestion e g toxic or neurogenic increase in capillary permeability [27]

PATHOGENESIS OF CHEYNE STOKES RESPIRATION

Two factors are concerned in the development of Cheyne-Stokes respiration (1) a diminished sensitivity of the respiratory center and (2) a relatively inadequate concentration of carbon dioxide to stimulate the respiratory center

Diminished Sensitivity of Respiratory Center

Cheyne-Stokes respiration is not a specific feature of congestive heart failure It is seen most frequently in patients with cerebral tumors and other cerebral lesions and in elderly patients with cerebral atherosclerosis who receive morphine or other strong cerebral depressants factors which may diminish the sensitivity of the respiratory center Congestive heart failure itself is associated with diminished sensitivity of the respiratory center [110] Sleep is a predisposing factor because it is associated with a diminished sensitivity of the respiratory center The relief of Cheyne-Stokes respiration by aminophylline is probably due to direct or indirect stimulation of the respiratory center The cerebral blood flow is diminished by aminophylline, this may result in increased carbon dioxide tension in the respiratory center [111]

Inadequate Respiratory Stimulus (Acapnia)

With *severe* depression of the respiratory center even a normal content of carbon dioxide in the blood may be insufficient to stimulate the center, following temporary apnea periodic breathing may be induced With lesser degrees of medullary depression Cheyne-Stokes respiration is precipitated only if there is a reduction in the carbon dioxide tension i e, if there is a diminution in the normal respiratory stimulus In cases of congestive heart failure with dyspnea overventilation results in an excessive pulmonary elimination of carbon dioxide and consequent reduction in its arterial concentration (acapnia) When diminished responsiveness of the respiratory center (due to sleep morphine, cerebral arteriosclerosis) is combined with a deficient respiratory stimulus (due to hyperventilation in left sided heart failure) a period of apnea is produced and periodic breathing follows

The Cycle of Cheyne Stokes Respiration

The subsequent waxing and waning of periodic respiration is explained as follows During the initial apnea there is a progressive reduction in arterial oxygen saturation, Arterial hypoxemia stimulates the carotid sinus and thereby the respiratory center to resume respiration At the same time an increase in carbon dioxide tension during the apneic phase directly stimulates the respiratory center This sudden and exaggerated stimulation of the respiratory center by both hypoxemia and excess of carbon dioxide results *in an overshooting of the crescendo phase of* respiration, with resulting hyperpnea This exaggerated hyperpnea again excessively reduces the carbon dioxide content of the blood and is followed by waning respiration apnea and a repetition of the cycle

The importance of the carbon dioxide content of the blood in the pathogenesis of Cheyne-Stokes respiration is indicated by the following observations Cheyne-Stokes respiration can be induced by voluntary overventilation which reduces the blood carbon dioxide tension [5], overventilation in an atmosphere containing 5 per cent carbon dioxide fails to cause this type of periodic breathing, the administration of carbon dioxide abolishes Cheyne-Stokes respiration [3] the carbon di

oxide tension of arterial blood is reduced in patients with Cheyne-Stokes respiration [50]

Arterial Hypoxemia

Arterial hypoxemia does not initiate the attack [42] for the oxygen saturation is normal in patients with heart failure who are subject to Cheyne-Stokes respiration and the administration of oxygen does not abolish the attack [4] But arterial hypoxemia is important in causing the crescendo phase after apnea has been initiated by a reduction in carbon dioxide in a patient with a hyposensitive respiratory center Oxygen given during Cheyne-Stokes breathing only modifies it by prolonging the apnea and making the hyperpnea less stormy [116] For the anoxic stimulus to overventilation is removed and the latter is produced only by the excessive carbon dioxide which accumulates during apnea

Cheyne Stokes Respiration and the Adams Stokes Syndrome

Cheyne-Stokes breathing sometimes occurs in connection with the Adams-Stokes syndrome in complete heart block During the prolonged period of cardiac arrest cerebral ischemia depresses respiratory irritability At the same time the arterial hypoxemia which develops during circulatory standstill results in hyperventilation and excessive elimination of carbon dioxide When the heart resumes beating the respiratory center is relatively insensitive and the blood which is propelled to it is deficient in carbon dioxide These are the factors initiating the apnea of Cheyne-Stokes respiration Hyperpnea and dyspnea occur during cardiac standstill and apnea during resumption of cardiac contraction

PATHOGENESIS OF CARDIAC EDEMA

Sodium Water Retention

Cardiac edema has long been attributed primarily to an increased venous pressure and consequently to an elevated hydrostatic pressure within the capillaries [115, 77] In recent years emphasis has shifted to the importance of sodium and water retention within the body for without it generalized edema cannot occur It is apparent from the rapid large increase in weight with the development of edema and the similar loss of weight with disappearance of edema that edema formation depends on a positive external fluid balance

Transudation of the normal quantity of plasma fluid from the capillaries into the interstitial fluid cannot possibly account for the vast quantity of edema fluid which often equals many times the total quantity of plasma (p 168) Therefore capillary transudation of plasma filtrate can continue to form such quantities of edema fluid only if the plasma is continually replaced by concomitant renal retention of fluid

The discovery that in congestive heart failure there is an impaired renal excretion of sodium (p 169) has called attention to the importance of the kidney in the edema of heart failure (p 171) The therapeutic efficacy of extreme reductions in sodium intake and likewise of mercurial diuretics which produce a notable increase in sodium excretion has reinforced the belief that sodium balance is the cardinal factor in the production and disappearance of edema Similarly the production of edema in patients with Addison s disease by excessive dosage of desoxycorticosterone and sodium (p 173) stresses the importance of both sodium and renal function because desoxycorticosterone promotes renal tubular reabsorption of sodium

The possible manner in which cardiac failure impairs the renal excretion of sodium and water and leads to edema has been discussed in detail (p 171) In the same chapter the relative importance of sodium water retention and of elevated venous pressure in the pathogenesis of cardiac edema was considered In brief it was concluded that sodium water retention is a prerequisite for the development of edema but edema is not necessarily a *direct* consequence of salt-water retention Hypervolemia increased venous return to an incompetent cardiac chamber and increased venous and capillary pressure are a sequence of events which determine the appearance and localization of edema after renal retention of sodium and water occur According to the Starling theory an increased venous and capillary pressure first induces transudation of plasma fluid and reduction of plasma volume which somehow then lead to retention of sodium and water and edema formation

Increased Venous Pressure

The studies of Starling[115] showed that a passage of fluid from the capillaries into the tissues occurred when the hydrostatic pressure within the capillaries exceeded the colloid osmotic pressure of the serum protein Thus the accumulation of fluid in the tissues may be due either to an elevation of capillary hydrostatic pressure or to a diminution of

serum proteins or both Normally there is a gradual fall of pressure as the blood passes from the arterial limb to the venous limb of the capillaries and thence to the great veins According to the direct microscopic studies of Landis [67] the pressure in the arterial limb of the human capillary is about 42 cm of water and in the venous limb about 16 cm of water Since the colloid osmotic pressure is about 30 cm of water the equilibrium between the two factors is normally such as to cause fluid transudation into the tissues at the arterial limb and fluid resorption at the venous limb

The normal pressure in a medium sized subcutaneous vein is about 4 to 8 cm of water In cases of heart failure associated with subcutaneous edema the venous pressure commonly rises to between 15 and 25 cm of water and sometimes higher According to the studies of Fahr and Ershler,[37] who used Landis' method for measuring capillary pressure edema tends to develop when the hydrostatic pressure in the venous end of the capillary is 26 cm of water which corresponds to a pressure in the arm vein of 17 cm of water There is a corresponding rise in the hydrostatic pressure of the capillaries so that it greatly exceeds the colloid osmotic pressure of the blood in the venous as well as the arterial limb The result is a transudation of fluid into the tissue spaces with consequent edema

The belief that edema forms because of increased venous (and therefore capillary) hydrostatic pressure is based on considerable experimental and clinical evidence [106] Venous ligation in animals and humans, which causes a local rise in venous pressure, has resulted in edema of the affected subcutaneous tissues [21] Landis[67] showed that when the hydrostatic pressure in the capillaries of the frog s mesentery exceeded the colloid osmotic pressure of the blood there was a transudation of fluid out of the capillaries Quantitative plethysmographic studies on humans by Krogh Landis and Turner[63] revealed that after compression of an extremity fluid accumulated in the tissue spaces when the venous pressure exceeded 15 to 20 cm of water, a pressure similar to that seen frequently in patients with right sided heart failure

The importance of an elevated venous pressure in causing cardiac edema is demonstrated clinically by the frequency of edema in patients with right sided heart failure, in whom the elevated venous pressure is a characteristic feature and by the absence of subcutaneous edema in patients with left-sided heart failure whose systemic venous pressure is normal On the other hand, pulmonary edema occurs frequently in cases of isolated left sided heart failure in which an elevation of the venocapillary pressure is limited to the pulmonary circulation That a diminished blood supply to the tissues is not a causative factor appears clear from the absence of edema in patients with shock due to acute circulatory failure The greater frequency and intensity of cardiac edema in the lower extremities of ambulant patients may also be explained by the higher venous and capillary pressure due to gravity In normal subjects the average venous pressure in the lower extremities was found to be 12 cm water in recumbency 56 cm in the sitting and 86 cm in the standing position and 23 cm during walking [98]

The essential causal relationship of an elevated venous pressure to cardiac edema has been questioned particularly by those who oppose the backward failure hypothesis Altschule[1] emphasized that while in general there is a correlation between increased venous pressure and the presence of edema there is considerable overlapping of the values of venous pressure in edematous and non edematous patients In many edematous patients the venous pressure was no higher than in patients without edema Only when the venous pressure rises as high as 30 to 40 cm of water does Altschule believe it may be considered solely responsible for the formation of cardiac edema One possible explanation for these discrepancies is the variation in venous pressure according to the patient s activity [81] Isolated measurements of venous pressure made with the patient at rest do not reflect these variations Shifts in edema fluid occur much more slowly than changes in venous pressure dependent on rest and exercise Variations in sodium intake tissue pressure and other secondary factors may also account for incomplete correlations between degree of elevation of venous pressure and of edema

Despite any objections increased capillary hydrostatic pressure together with increased sodium water retention appears to be a major factor in the pathogenesis of cardiac edema Sodium water retention without ele

vation of venous pressure causes edema only in exceptional circumstances Conversely when sodium water retention is markedly inhibited by severe restriction of sodium intake increased capillary hydrostatic pressure can only cause a limited transfer of plasma fluid to interstitial fluid and only a limited degree of edema Increased venous (or capillary) pressure may also indirectly influence the formation of edema by actually stimulating the renal retention of sodium and water (p 171)

Reduction in Colloid Osmotic Pressure

Normally the force of hydrostatic pressure which tends to cause an escape of fluid from the capillaries is counterbalanced by the colloid osmotic pressure of the blood proteins which tends to draw fluids from the intercellular tissue into the capillaries The colloid osmotic pressure develops because the blood is separated from the intercellular tissue fluids by a membrane (the capillary wall) which is relatively impermeable to protein The plasma albumin is most important in producing osmotic pressure because its concentration is greater than that of the globulin and because its molecule is smaller The normal colloid osmotic pressure is between 30 and 34 cm of water which is about equal to the average hydrostatic capillary pressure less than the capillary pressure at the arterial end and more than the venocapillary pressure

A sharp reduction in blood proteins especially in plasma albumin and the resulting diminution in osmotic pressure may permit the unbalanced hydrostatic capillary pressure to cause an escape of fluid into the tissues Subcutaneous edema has been produced experimentally in animals by plasmapheresis [7] The edema associated with certain nephrotic states and with starvation has been attributed to the very low blood proteins in these conditions But there is often a lack of correlation between the severity of the edema and the diminution in proteins the edema may disappear while the proteins are still low

In cases of congestive heart failure there is often a reduction in the concentration of plasma protein especially of the important albumin fraction [104, 82] In general the reduction in blood proteins in most cases of heart failure is relatively small but occasionally it is pronounced as in cases of constrictive pericarditis A corresponding diminution in the colloid osmotic pressure was demonstrated by the direct measurements of Iversen and Nakazawa [86]

According to Payne and Peters [91] the reduction in plasma proteins is caused chiefly by malnutrition due to anorexia low protein intake and vomiting Pronounced passive congestion of the intestinal mucosa may somewhat impair the absorption of amino acids Prolonged loss of small amounts of albumin in the urine and in pleural and peritoneal exudates may also decrease serum albumin Increase in plasma volume may diminish the concentration of albumin Finally longstanding congestion and anoxemia of the liver may impair its ability to elaborate serum protein but Bauman et al [8] in measurements of exchangeable albumin by means of I^{131} labeled albumin found no significant alteration in albumin synthesis by patients with congestive heart failure A reduction in serum proteins does not in itself cause edema unless the concentration falls below 5 gm per 100 cc (albumin below 2 5 gm per 100 cc) Therefore the lesser degrees of hypoproteinemia often seen in patients with congestive heart failure are usually insufficient to produce edema and at most represent a minor accessory causative factor But when hypoproteinemia is pronounced correction of this factor may be important in controlling edema

The colloid osmotic pressure of serum protein is somewhat neutralized by the osmotic pressure of the protein in tissue fluid However the protein content of the latter is much less (about 0 5 per cent) than that of serum protein and its osmotic pressure is only about 3 cm of water as compared to 30 cm for the colloid osmotic pressure of the blood The effective colloid osmotic pressure tending to draw fluid into the capillaries would be 27 cm of water Occasionally the protein content of tissue fluid is greatly increased e g when there is lymphatic obstruction because the lymphatics serve to return protein from the tissue spaces to the veins [80] Under such circumstances edema formation is greatly facilitated because the effective colloid osmotic pressure in the blood is reduced by the high colloid osmotic pressure of tissue fluid However this factor is not important in the edema of congestive heart failure

Tissue Pressure

The extracapillary tissues themselves exert a force which resists their distention by fluid

This force is known as tissue pressure It partially counteracts the capillary hydrostatic pressure and thus resists the formation of edema[88, 170] Normally this measures about 3 or 4 cm of water and is greater in the lower extremity than in the upper[103] Low tissue pressure in certain sites such as in the loose tissue of the eyelids promotes the accumulation of fluid there A reduction of tissue pressure in cachectic and bedridden patients with lax subcutaneous tissues and in those whose tissues have been stretched by previous episodes of edema predisposes to the accumulation of edema Such a reduction in tissue pressure probably exists in inactive or bedridden cardiac patients but at most it is an accessory factor in the development of cardiac edema It may however, partly account for some of the imperfect correlations between elevated venocapillary pressure and edema formation

Lymphatic Drainage

Normally the lymphatics are concerned in the removal of tissue fluid and especially of the tissue proteins which have seeped through the capillary wall In patients with cardiac edema this lymphatic flow is impaired due perhaps to the elevated venous pressure which prevents lymphatic emptying into venous channels[80] It is uncertain whether this is of much importance in cardiac edema because the protein content of cardiac edema fluid is low whereas edema fluid caused by lymphatic obstruction contains a high concentration of protein

Capillary Permeability

An increased capillary permeability can be an important factor in producing edema because it permits the escape of proteins with a consequent diminution in the colloid osmotic pressure of the blood and an increase in the colloid osmotic pressure of the tissues Its importance as a factor in cardiac edema has been variously evaluated Ordinarily permeability of a membrane refers to the size of the particles which diffuse through it The capillaries normally permit free diffusion of salts and water but are relatively impermeable to plasma proteins and lipoproteins Therefore minimal quantities of the latter are found in interstitial tissue whereas the various cations and anions appear in concentrations which are determined by Donnan s equilibrium and therefore differ only very slightly from their concentrations in plasma Increased capillary permeability should therefore indicate the diffusion of more than normal quantities of protein and lipoproteins into the interstitial fluid By this definition, as we shall see in the next paragraph, there is no evidence of significant increase in capillary permeability in heart failure On the other hand, Smirk[13] adduced some evidence suggesting an 'increased capillary permeability' to salts and water in heart failure He experimentally elevated the venous pressures of normal persons and of persons with cardiac failure to levels equally in excess of the measured colloid osmotic pressure Despite the same pressure difference he observed a greater accumulation of edema fluid in the cardiac patients He concluded that the capillaries of patients with cardiac failure were more permeable than those of normal persons Burch Reaser and Cronvich,[16] in studies following the intravenous injection of Na^{24} discovered not only an amazing rapid diffusion of sodium through the capillary wall but also that this rate of diffusion was twice as rapid in patients with heart failure as in normal subjects But this increase in diffusion of sodium is not to be construed as an increase in capillary permeability, it can more readily be explained by increased hydrostatic pressure and other factors in cardiac edema already enumerated

The presence of increased capillary permeability in heart failure is suggested by the experiments of Landis[86] who found that capillaries are rendered permeable to protein when deprived of oxygen for three minutes Anoxemia of the capillaries with right sided heart failure is assumed to result from prolonged peripheral stasis Increased permeability in anoxemic capillaries may also be due to vasodilatation with consequent augmentation of the filtering surface Despite these experimental studies and theoretical considerations clinical observations indicate that the factor of increased capillary permeability is not significant in causing cardiac edema In many patients with cardiac edema the oxygen saturation of the blood is normal or only slightly reduced Conversely there is usually no edema in cyanotic patients with congenital heart disease or advanced emphysema despite a low oxygen saturation The degree of anoxia represented by Landis[86] experiments is rarely attained in congestive heart failure The most important objection to the theory of capillary permeability is the low content of

protein (0 2 to 0 5 per cent) in edema fluid [118] Nor is there any change before or after compensation This indicates that there is relatively little increase in capillary permeability an increase which is of only secondary importance in causing cardiac subcutaneous edema On the other hand, varying degrees of permeability in different regions of the body may account for the predominant distributions of capillary transudations e g , the relative intensities of subcutaneous edema and ascites

Hormones

It is known that the pituitary antidiuretic hormone is important in controlling water balance, but little is known of any possible relation to cardiac edema (p 174) The anterior pituitary and adrenal cortical hormones have also been implicated in the production of cardiac edema by their influence on renal retention of sodium The production of edema by the administration of desoxycorticosterone and salt to patients with Addison s disease has been noted The possible role of the adrenal cortical hormone in the renal retention of sodium in patients with heart failure has been discussed (p 173)

PATHOGENESIS OF CARDIAC HYDROTHORAX

The accumulation of fluid in the pleural cavities (hydrothorax) in the course of congestive heart failure is due to the same factors which cause subcutaneous edema The factor of increased capillary permeability is relatively more important in the development of hydrothorax than as a cause of anasarca as seen from the higher content of protein in the pleural fluid (2 to 3 per cent instead of 0 2 to 0 5 per cent) Despite the greater permeability of the pleural capillaries hydrothorax occurs less commonly than subcutaneous edema probably because the pleural vessels drain into both the systemic circulation (by way of the azygos veins and the superior vena cava) and into the pulmonary circulation (by way of the pulmonary veins) Thus any tendency to elevation of the pressure within the pleural capillaries because of an elevated venous pressure in one of the circulations (isolated right-sided or isolated left sided heart failure) is compensated by a free drainage into the other system Hydrothorax is most often seen in cases of combined right- and left sided heart failure in which there is back pressure in the pleural capillaries due to venous engorgement in both circulations

There is no generally accepted nor completely satisfactory explanation for the occurrence of hydrothorax more frequently on the right side than on the left The classic explanation held that with enlargement of the right side of the heart the vena azygos major was compressed against the root of the right lung But the anatomic studies of Fetterolf and Landis[23] indicated that such compression is extremely unlikely These observers believed that left-sided effusions result from compression of the left pulmonary veins by a large left atrium and right sided effusions from compression of the right pulmonary veins by a large right atrium

PATHOGENESIS OF ASCITES

Ascites like the transudate in the pleural cavities, is due *fundamentally to the increased* venous pressure which accompanies right-sided heart failure Here too however increased permeability is relatively more important than in the formation of edema because as Salvesen and Linder[104] have shown the ascitic fluid contains 2 to 3 per cent of protein as compared with less than 0 5 per cent in edema fluid Despite this ascites occurs less often than subcutaneous edema and later in the course of congestive heart failure

The greater permeability of the peritoneal capillaries is usually more than offset by the higher pressure in the subcutaneous capillaries, especially in the lower extremities Since patients with cardiac edema often move about while in the early stages of right sided heart failure the factor of gravity causes a greater elevation of venous pressure in the tissues of the lower extremities than in the venules of the peritoneum Even later when the patient sits in a chair or at the side of his bed or propped up in bed because of orthopnea there is a relatively greater capillary hydrostatic pressure in the lower extremities than in the peritoneum

Ascites appears to be more closely related to increase in hepatic capillary pressure and increased permeability of these vessels than to increased hydrostatic pressure and permeability of other peritoneal vessels The high protein composition of ascitic fluid is virtually identical with that of hepatic lymph

Ascites is especially prominent and often

occurs earlier than overt subcutaneous edema in heart failure associated with constrictive pericarditis or tricuspid stenosis In these cases hepatic congestion is especially intense and cardiac cirrhosis not uncommon These observations suggest that the relative degree of hypertension of the hepatic capillaries is a determining factor in the occurrence and prominence of ascites There is evidence that neither portal vein ligation with portal hypertension nor inferior vena caval ligation caudad to the liver is followed by ascites, but that the latter may be induced by inferior vena caval ligation above the level of the liver or by hepatic vein ligation [78, 117]

Other factors are important or contribute to the development or maintenance of ascites Abnormal sodium and water retention by the kidney is essential Marked restriction of sodium intake and the administration of mercurial diuretics greatly limit or prevent the recurrence of ascites The loss of protein in ascitic fluid reduces the plasma albumin and the colloid osmotic pressure thus accentuating the effect of the increased capillary hydrostatic pressure Disturbances in lymphatic flow and hormonal factors may also contribute to the formation of ascites

PATHOGENESIS OF CYANOSIS

The blue coloration of the skin which cyanosis signifies is due to the reduced hemoglobin of the blood The intensity of cyanosis depends on (1) the amount of reduced hemoglobin in the blood and (2) the amount of blood visible in the superficial vessels of the skin

THE AMOUNT OF REDUCED HEMOGLOBIN IN THE BLOOD

The studies of Lundsgaard and Van Slyke[75] revealed that cyanosis usually appears when the amount of reduced hemoglobin in the blood exceeds 5 gm per 100 cc The concentration of reduced hemoglobin in the blood depends on the total amount of hemoglobin in the blood and the percentage of the latter which is uncombined with oxygen

Total Hemoglobin Content

Normally there are about 15 gm of hemoglobin per 100 cc of blood Cyanosis occurs if one third or more of this is uncombined with oxygen (5 gm or more per 100 cc of reduced hemoglobin), i e, if there is less than 66⅔ per cent oxygen saturation of the blood in the superficial vessels of the skin In patients with polycythemia, whose total hemoglobin is 20 gm per 100 cc, cyanosis would appear even if the oxygen saturation were 75 per cent (25 per cent unsaturation of 20 gm = 5 gm reduced hemoglobin) On the other hand extreme oxygen unsaturation is necessary to produce cyanosis in anemic patients If the total hemoglobin content is less than 33 per cent of normal (i e less than 5 gm per 100 cc), cyanosis cannot occur even if there is complete oxygen unsaturation i e, even if all the hemoglobin is in the reduced form

Degree of Oxygen Unsaturation

Since 1 gm of hemoglobin is capable of combining with 1 33 cc of oxygen the blood with a normal hemoglobin content (15 gm per 100 cc) has an oxygen capacity of 20 volumes per cent Actually the arterial blood (ie, after pulmonary oxygenation) contains 19+ volumes per cent of oxygen or is 95+ per cent saturated This means that there is 1 volume per cent of oxygen unsaturation of the arterial blood In passing through the tissues the blood loses an additional 5 volumes per cent of oxygen so that the venous blood has an oxygen unsaturation of 6 volumes per cent While the loss of oxygen in the capillaries is uneven, we may consider the average of the arterial and venous oxygen unsaturation $\frac{1 \text{ vol} + 6 \text{ vol}}{2}\left(= 3\frac{1}{2} \text{ volumes per cent}\right)$ as representing the average oxygen unsaturation of the capillary blood in the skin Cyanosis occurs with normal total hemoglobin content when the capillary oxygen unsaturation exceeds 6½ to 7 volumes per cent this represents 5 gm of reduced hemoglobin

This degree of oxygen unsaturation may be due to (1) inadequate pulmonary oxygenation of the blood (2) excessive loss of oxygen from the capillary blood in the tissues or (3) mixing of venous and arterial blood due to a congenital cardiovascular deformity

Cyanosis due to inadequate pulmonary oxygenation is encountered in cases of severe emphysema, kyphoscoliosis with pulmonary atelectasis pulmonary fibrosis extensive pulmonary embolization and other pulmonary disease (Chap 39)

Mild cyanosis is common in mitral stenosis in which pulmonary congestion of long duration leads to extensive fibrosis of the lung with consequent interference with oxygenation In patients with left ventricular failure there

is usually no significant arterial hypoxemia unless there is associated pulmonary edema pneumonia or other pulmonary complications which may cause cyanosis When cyanosis is present in patients with right sided heart failure it is due either to the pulmonary lesions mentioned or to the associated pulmonary congestion of left sided heart failure Oxygen therapy relieves or dispels cyanosis only to the extent that it is due to inadequate pulmonary oxygenation

Increased deoxygenation of the capillary blood contributes to cyanosis in patients with right sided heart failure It is due chiefly to slowing of the blood flow in the tissue capillaries Cyanosis may occur even with normal pulmonary oxygenation e g if 13 volumes per cent of oxygen are extracted from the capillary blood instead of the normal 5 volumes For then the average capillary oxygen unsaturation would be $\frac{1 + 14}{2} = 7\frac{1}{2}$ Often there is a combination of inadequate pulmonary oxygenation and increased capillary deoxygenation In patients with extremely diminished cardiac output especially those with acute circulatory failure cyanosis may be due chiefly to capillary deoxygenation

Cardiovascular Shunts Capillary hypoxemia sufficient to cause cyanosis may occur despite normal pulmonary oxygenation and normal capillary deoxygenation when an abnormal cardiovascular shunt causes a significant mixing of venous and arterial blood This occurs in patients with congenital cardiac malformations (p 731) such as the tetralogy of Fallot septal defects or transpositions of the great vessels Lundsgaard and Van Slyke[75] calculated that in the absence of other abnormalities cyanosis occurs if the amount of venous arterial shunt is more than about 38 per cent of the total cardiac output Less than this is necessary if as is usual there is an associated polycythemia or if pulmonary or peripheral stasis due to cardiac failure contributes to the oxygen unsaturation of the blood In many patients with congenital cardiac deformities the higher pressure in the left side of the heart as compared with the right directs the blood from the arterial to the venous side of the shunt But as a result of exercise pneumonia progressive increase in pulmonary arteriolar resistance congestive heart failure or other factors the pressure on the right side of the heart may be elevated sufficiently to produce a venous arterial shunt with the consequent development of cyanosis

THE AMOUNT OF BLOOD VISIBLE IN THE VESSELS OF THE SKIN

The intensity of cyanosis depends on the amount of reduced hemoglobin in the blood actually visible through the skin Therefore cyanosis is most readily observed where the overlying skin is very thin e g the nail beds the lips the tip of the nose the cheek bones and the ears Cyanosis is more intense the more blood and therefore the more reduced hemoglobin is actually in the vessels of the skin This in turn is greater the more numerous and the more dilated are the capillaries and venules of the skin

The state of the subpapillary venous plexus is much more important in causing cyanosis than that of the superficial capillary loops for the former presents a greater area parallel to the skin Mechanical distention of the subpapillary venules in healthy persons by compression of the arm veins can produce cyanosis even though there is a normal oxygen saturation, for although the amount of reduced hemoglobin is not elevated the amount visible is greatly increased In patients with congestive heart failure similar distention of the subpapillary venules is caused by the elevated venous pressure

FACTORS MODIFYING CYANOTIC HUE

The blue color of the skin in cyanotic patients with heart disease may vary in hue and intensity In patients with polycythemia the skin is purple or reddish blue because there is an increase in the red of the oxyhemoglobin as well as in the blue of reduced hemoglobin A pale ashen or leaden type of cyanosis is seen when the superficial cutaneous vessels are constricted and relatively empty of blood This is seen in patients with acute circulatory failure or whenever there is a sharp reduction in the cardiac output The cyanosis is then due to the reduced hemoglobin in the less visible deeper venous plexus below the skin In patients with tricuspid valvular disease and heart failure the blue of cyanosis is often mingled with the yellow color due to icterus

PATHOGENESIS OF ICTERUS IN HEART DISEASE

Jaundice is due to an excessive amount of bilirubin in the blood serum While hyper

bilirubinemia is present in many patients with congestive heart failure, it is sufficient to produce jaundice only in about 4 per cent of them, *most often in those with combined mitral and tricuspid valvular disease* [84] The significant clinical features of these cases with jaundice are severe and longstanding passive congestion of the lungs and the liver and the great frequency of pulmonary infarction[59, 100] (see p 000)

There is evidence that the hyperbilirubinemia is due to impairment of liver function This is indicated not only by the hyperbilirubinemia itself but also by the increase in urobilinogen in the urine and by various tests of hepatic function (p 00) As a rule the elevated serum bilirubin concentration is due to a mixture of quick reacting (direct) and slow-reacting (indirect) bilirubin [107] In patients *with frank jaundice associated with heart* failure there is a prompt and direct van den Bergh reaction but some patients with heart failure have a slight hyperbilirubinemia and an indirect van den Bergh reaction The impairment of liver function may be due to oxygen deficiency, and this in turn is caused chiefly by prolonged stasis of blood in the congested liver and occasionally perhaps, by deficient pulmonary aeration in consequence of extensive pulmonary infarction Both the hepatic blood flow and oxygen consumption are reduced in heart failure [88] The hepatic venous blood was found to be markedly unsaturated with oxygen [89] Clinical observations suggest that jaundice and presumably *hepatic damage in congestive heart failure are* correlated with *very* high venous pressure and prolonged duration of the latter Sherlock[111] suggested that high venous pressure may produce mechanical obstruction of the bile canaliculi with regurgitation jaundice

Hyperbilirubinemia and jaundice are caused to some extent also by excessive production of bilirubin for there is an increased quantity of urobilin in the stools as well as of urobilinogen in the urine The increase in formation of bilirubin may result from excessive destruction of blood in the lung the blood representing either infarcted areas or the red blood cells extravasated in the pulmonary alveoli Evidence of increased destruction of blood is seen clinically in the expectoration of heart failure cells and at necropsy in the deposition of hemosiderin the brown iron pigment, within the lung (brown induration) But the destruction of extravasated erythrocytes could only explain an increase in indirect bilirubin, whereas in heart failure direct bilirubin is increased to an even greater degree While pulmonary infarction may play a role in causing jaundice both by producing arterial anoxemia and by increasing the formation of bilirubin, it is not an essential factor, as jaundice in patients with heart failure may occur in its absence [8]

PATHOGENESIS OF GALLOP RHYTHM

(See p 69)

PATHOGENESIS OF PULSUS ALTERNANS
(Alternation of Pulse, Cardiac Alternans)

Pulsus alternans is an evenly spaced alternation of strong and weak cardiac or pulse beats It occurs most frequently in cases of left ventricular failure, especially those due to *hypertension or coronary atherosclerosis, but* it has been observed also in association with atrial or ventricular tachycardia Electrical alternans [84] which refers to alternation in size of the QRS or T complexes occurs in these conditions and also as a result of digitalis intoxication [87]

Pulsus alternans is distinguished from the sequence of strong and weak beats of pulsus bigeminus (p 000) by the fact that the weak beat in pulsus alternans is very slightly closer to the succeeding beat than to the preceding The weak premature beat of pulsus bigeminus is distinctly closer to the preceding normal beat

A detailed discussion of the pathogenesis of pulsus alternans may be found in the monographs of Poumailloux[93] and of Kisch [61]

The alternation in pulse is most generally attributed to a corresponding alternation in the strength of ventricular contraction and therefore in the amount of blood ejected into the peripheral arteries The interval between beats is approximately unchanged but the weak beat is slightly delayed due to slower transmission of the pulse wave In the electrocardiogram the cycle lengths are equal * The alternation in strength of cardiac contraction is believed to be due to disease or fatigue of many cardiac fibers as a result of which there is a variation in excitability or refractoriness During the strong beat most of the fibers respond but the others are refractory, during

* Friedman [36] observed that the cycle lengths are only approximately equal the cycles after the strong beats being slightly longer (I y 01–03 sec) than those after the weak beats

the weak beat fewer fibers contract including tho e which were previously refractory [12] The basic cause of pulsus alternans is severe dam age of the ventricular myocardium with im pairment of its contractility Blumberger[11] observed that the smaller systoles had a longer time of isometric contraction an anacrotic elevation of longer duration and a shorter ejection time in comparison with the larger systoles

Of interest is the observation that pulsus alternans may be initiated by a premature beat usually in cases with tachycardia in which the diastolic period is shortened The premature beat further shortens the brief diastole and significantly reduces the degree of filling and leaves many fibers refractory The subsequent compensatory pause permits greater filling and myocardial recovery Thus an alternating pattern of contraction may be initiated When associated with a tachycardia but without organic disease pulsus alternans is usually relatively benign in contrast with its serious prognostic implication in cases of left sided heart failure

Chapter 10

CIRCULATORY AND RELATED MEASUREMENTS

THE CARDIAC OUTPUT

The cardiac output is the effective volume of blood expelled by either ventricle of the heart in a unit of time This is expressed as cubic centimeters or liters per minute The output of the two ventricles is usually identical, for the weaker musculature of the right ventricle is counterbalanced by the lesser resistance against which it works If there is a regurgitation of blood due to aortic valvular insufficiency or a shunting of blood due to congenital defects the actual output of the heart may be greater than the effective output The volume of the circulation the minute volume and the rate of circulation are used synonymously with cardiac output I prefer the latter term because of its more common usage and because the other terms may be confused with blood volume and circulation time The output of each ventricle per beat is known as the stroke output and ranges between 60 and 100 cc with an average of 75 cc when the heart rate is 72 per minute The cardiac output is equal to the stroke output multiplied by the cardiac rate Thus an increase in cardiac output may be effected by an increased stroke output an increased cardiac rate or both

MEASUREMENT OF THE CARDIAC OUTPUT

The cardiac output may be determined by

(1) Direct application of the Fick principle

(2) Dilution methods including use of foreign gases and dyes

(3) Physical methods

The Fick Principle

Fick[67] pointed out that the amount of blood traversing the pulmonary capillaries in a unit of time is a measure of the cardiac output (from the right ventricle) Since the diffusion of oxygen or carbon dioxide across the pulmonary alveolar walls depends on the pulmonary blood flow the latter can be determined from the amount of oxygen absorbed in a unit of time and the difference in oxygen concentration of the blood before and after leaving the lungs i e the arteriovenous oxygen difference It is assumed that the amount of oxidation in the lungs is negligible Thus if the oxygen concentration of the arterial blood is 190 cc per liter and that of the venous blood 150 cc per liter each liter of blood absorbs 40 cc of oxygen If 200 cc of oxygen are absorbed by the subject in one minute $\frac{200}{40}$ or 5 liters of blood must have flowed through the lungs in a minute in order to absorb this quantity of oxygen This pulmonary blood flow is the right ventricular output which is presumed to equal the left ventricular or cardiac output

Expressed mathematically

$$\text{Cardiac Output (liters per min)} = \frac{O_2 \text{ absorption (cc per min)}}{\text{Arterial } O_2 - \text{mixed venous } O_2 \text{ (cc per liter)}}$$

The cardiac output may be similarly calculated from the total carbon dioxide elimination in a unit of time and the arteriovenous carbon dioxide difference

$$\text{Cardiac Output (liters per min)} = \frac{CO_2 \text{ elimination (cc per min)}}{\text{Venous } CO_2 - \text{arterial } CO_2 \text{ (cc per liter)}}$$

The Direct Fick Method

(a) *The oxygen absorption* in cubic centimeters per minute under basal conditions is determined with the aid of a basal metabolism machine (such as the Benedict Roth apparatus) For comparative cardiac outputs e g before and after exercise the oxygen consumption can be determined from 2 or 3 minute samples of expired air collected in

Douglas bags analyzed in an Haldane apparatus and measured in a Tissot spirometer

(b) The *oxygen content of arterial blood* is found by direct puncture of a convenient artery such as the brachial, radial or femoral. An indwelling needle permits repeated sampling if multiple cardiac outputs are to be determined during a period of study.

(c) The *oxygen content of mixed venous blood* can now be satisfactorily determined from blood samples obtained by intracardiac catheterization.

For mixed venous blood satisfactory specimens in hearts without shunts are best obtained from the pulmonary artery or right ventricle. Complete mixing may not occur in the right atrium because of independent laminar flow of blood from the superior and inferior vena cava which may differ in oxygen concentration, or because of proximity to the coronary sinus, the blood from which is much lower in oxygen content than mixed venous blood. Several specimens should be taken from various parts of the chamber and they should not differ by more than 0.5 volume per cent if they represent mixed venous blood. The oxygen determinations are made as on arterial blood (p. 227).

The cardiac output is then determined by substituting the values obtained in the Fick formula

$$CO = \frac{O_2}{\text{a-v oxygen difference}}$$

There is no serious criticism of the accuracy of the direct Fick method if the technique is properly carried out by a trained team and if every effort is made to keep the patient in a physiologic state.[217, 211] However, the technical requirements make this method impractical for general clinical usage. A method has been proposed for the direct measurement of the arteriovenous oxygen difference with the aid of a photoelectric colorimeter.[116] Recently Grossman et al.[95] devised a method for determining the cardiac output by the direct Fick principle with sodium aminohippurate (PAH) or para-acetylaminohippuric acid (PACA) as the test substance, avoiding the need for gas analysis.

Dilution Methods

A measured amount of foreign gas is inhaled or a dye or other substance is injected intravenously. The amount of blood flow in unit time required to absorb the measured uptake of gas or intravenously injected material represents the cardiac output.

Foreign Gases. The methods employing *nitrous oxide* have been described in detail by Lindhard,[135] the use of *ethyl iodide* by Starr and Gamble,[195] and that of *acetylene* by Grollman.[94] These foreign gas methods are subject to error[99] and are no longer used.

Intravenous Injection of Dyes. Hamilton and his co-workers[100] have determined the cardiac output by means of the rapid intravenous injection of brilliant vital red followed by the prompt withdrawal of repeated samples of blood from the femoral artery. More recently a blue dye has been employed. One cc. of 0.5 per cent Evans blue due (T-1824) is injected rapidly intravenously and blood samples are collected immediately and continuously through an indwelling arterial needle in the femoral artery which is connected with polyethylene tubing through which the blood flows into successive tubes revolving on a kymograph.[76, 156, 117] Samples are collected for about forty seconds. The dye may also be injected at a constant rate through a catheter into the right ventricle or pulmonary artery.[180] The samples of arterial blood are analyzed for dye concentration by means of a spectrophotometer. The cumbersome multiple determinations may be obviated by the use of an automatic recording device which employs a constant flow cuvette.[158] As the blood flows through the cuvette the light transmission varies with the concentration of the dye, producing a corresponding electric current, which is amplified and continuously recorded by a sensitive recording galvanometer. Adequate precaution must be taken to maintain a constant flow of blood, otherwise changes in light transmission will be induced by change in blood flow and not exclusively by change in dye concentration. The relatively high cost and elaborate nature of the apparatus at least partially neutralize its advantages.

The determined concentrations of dye are plotted as ordinates on semi-logarithmic paper with time in seconds as the abscissa. The time of recirculation is marked clearly by a sudden change in the direction of the concentration curve thus obtained. From the concentration curve the time of one circulation and the average concentration of the dye in that circulation are determined.[11] Since the quantity of dye injected is known and the time of the first circulation and the average

dye concentration are determined by the procedure the cardiac output can be calculated as follows

$$C\,O = \frac{60 \times I}{C \times T} \times \frac{100}{100 - H}$$

in which C O is the cardiac output I is the quantity of dye injected, C is the average dye concentration in one circulation T is the duration of one circulation in seconds and H the hematocrit

Although the underlying assumptions of this method have been questioned the values obtained check satisfactorily with those determined by the direct Fick method [101 2 0 53 154] Furthermore the dye dilution method possesses the advantages that oxygen consumption is not determined cardiac catheterization is not performed, and the cardiac output can be more readily determined during exercise [1 2] The intrathoracic and pulmonary blood volumes the circulation times and the volumes of the left atrium and ventricle[33] can be determined from the curve [148 100 156] Furthermore it is possible to make multiple measurements on the same patient when it would be difficult or impossible to catheterize the heart repeatedly as would be necessary with the direct Fick procedure

On the other hand the need for multiple arterial punctures or for an indwelling arterial needle and the laborious calculations have hitherto limited the practical usefulness of the dye dilution method for determining the cardiac output A photoelectric densitometer has been devised which records dye-dilution curves of T 1824 concentrations by measuring changes in optical density of a portion of the heat flushed ear and thus obviates the need for serial samples of arterial blood [145 186] By using a multiplier phototube the device effects a linear relationship between the deflection of the recording galvanometer and changes in arterial concentration of the dye Usually only 10 mg of T 1824 are used and determinations may be repeated at short intervals There is a close correlation between cardiac outputs determined by this technique and those determined by photoelectric measurements of dye concentrations in serial arterial blood specimens The cardiac output has been somewhat similarly determined by the use of a modified Millikan ear oximeter following injection of T-1824 [225 226 84] But larger quantities of the dye are required

Intravenous Injection of Radioisotopes

A new simple technique for measuring cardiac output has recently been reported [110] The method involves a single intravenous injection of human serum albumin tagged with radioactive iodine I^{131} Following the injection the counting rate is recorded from a narrow angle scintillation counter on the skin of the first left intercostal space in the parasternal line A count rate–time curve is obtained The area under the extrapolate curve divided into the count rate at equilibrium yields cardiac output in terms of the circulating blood volume The latter must be determined by one of the available methods (infra) The accuracy of the method remains to be verified The determination of the cardiac output by a continuous recording system of radioactivity in arterial blood utilizing iodinated (I^{131}) human serum albumin, had been previously reported [172]

Physical Methods

Physical methods of determining the cardiac output have the advantage of avoiding the necessity of arterial or venous punctures or of chemical determinations However, none of the methods employed have thus far provided uniformly accurate absolute values of cardiac output In general the calculations are standardized by comparison with the direct Fick procedure Hamilton[99] has given a detailed criticism of these methods

Three physical methods have been used in humans (1) X ray measurements, (2) pulse pressure and pulse wave measurements, (3) ballistocardiography

X ray Measurement of Cardiac Output The volume of the heart is determined roentgenographically in maximum systole and diastole by synchronization of the roentgen ray machine with an electrocardiograph The surface areas are measured with a planimeter and the volumes calculated therefrom by the use of Bardeen s formula [7] The combined cardiac output of the two ventricles is equal to the difference between the calculated systolic and diastolic volumes (stroke output) multiplied by the number of cardiac contractions per minute This value must be divided by 2 to obtain the cardiac output as usually defined i e the output of either ventricle [134]

Similar roentgenologic determinations of the cardiac output have been made with the aid of the kymograph[119] or electrokymograph [174 ■] By means of the electrokymo-

gram the ventricular thickness in systole and diastole can be determined, the stroke output is then calculated by a formula using these values Twelve per cent of cardiac outputs determined in dogs by this method were found to differ by more than 25 per cent from the outputs determined by the direct Fick method [178]

Rapid serial angiocardiography (p 15) may likewise be employed to determine the cardiac output

Pulse Wave and Pulse Pressure Measurements This physical method is based on the premise that the cardiac output varies approximately as the product of the pulse pressure, the arterial distensibility and the cardiac rate [84] The distensibility of the arterial system is determined from the pulse wave velocity and the diameter of the aorta

Boger and Wezler[25] advocated the following formula for calculating the stroke output

$$S\,O = \frac{2Q \times \Delta P \times L}{g a^2}$$

in which Q is the diameter of the aorta ΔP is the pulse pressure, L is the length of the arterial compression chamber receiving blood during systole, *g* is the specific gravity of blood and a is the pulse wave velocity in cm per second Simultaneous subclavian and radial pulse tracings are made from which the pulse wave velocity and L can be determined The diameter of the aorta is estimated from roentgenograms or is taken from statistical tables based on postmortem studies

The results obtained with these methods are of dubious reliability even though they are of value in comparative determinations in the same subject Often empiric modification of the calculated outputs are necessary to bring them in alignment with determinations of the cardiac output by gasometric or direct Fick procedures Considerable experience and meticulous care are necessary in the registration of the pulse waves and in the analysis and measurement of the curves obtained The measurements of aortic diameters based on postmortem studies are considerably below actual values during life

Ballistocardiograph Cardiac outputs determined with the high frequency, undamped and with the low frequency damped ballistocardiograph have checked satisfactorily with determinations made by right heart catheterization and the Fick principle in normal subjects [42, 24, 154] The ballistocardiograph is of particular value in determining rapid changes in output in the same subject On the other hand the ballistocardiograph is not useful for the clinical study of the cardiac output in sick patients The results are unsatisfactory in cases with output regurgitation as in aortic insufficiency in patients with arrhythmias or respiratory distress, in subjects who cannot hold their breath for a few seconds, and in those with pronounced tremor The ballistocardiograph cannot be used for measurement of the cardiac output in subjects whose tracings show bizarre complexes either because of cardiac disease or some other abnormality Because the subject must lie quietly during the recording the ballistocardiograph cannot be used to determine the cardiac output during exercise

The premise underlying the use of the ballistocardiograph for determining cardiac output has been criticized [99] The calculated values are inaccurate as absolute measures of the stroke output and must be modified empirically by comparison with the direct Fick method According to Cournand, Ranges and Riley[43] a considerable error is due to underestimation of the true diameter of the aorta due to the use of tables based on measurements after death They found that the ballistocardiogram gave results which were 18 5 per cent too low By measuring the diameter of the aorta after Diodrast visualization they obtained values for the cardiac output which corresponded closely to that obtained by the direct Fick procedure

THE CARDIAC OUTPUT IN HEALTH AND DISEASE

The cardiac output under basal conditions (i e, with the body recumbent at rest, at least twelve hours postprandially and in a room at 20 C) varies between 4 and 7 liters, with an average of 5 3 liters [196] These values were obtained with the direct Fick method and cardiac catheterization but similar values have been obtained by the intravenous dye dilution method [101, 156, 117] The corresponding stroke outputs average between 70 and 80 cc

The normal value for cardiac output is more constant when expressed in terms of the surface area and averages 3 2 liters per square

meter It is somewhat higher in children The minute cardiac output per square meter is known as the *cardiac index*

The percentage of the cardiac output distributed to individual organs varies with their needs at any given moment When the requirements of an organ increase its arterioles open in response to the local accumulation of metabolic waste products or to local or axon reflexes and more of the cardiac output of blood flows to that organ With reduced activity, a reversal of these mechanisms causes arteriolar constriction and a diminution of blood flow

Determinations of the blood flow to various organs have yielded the following results

Coronary blood flow	0 25 liter per minute [95]
Renal blood flow	1 3 liters per minute[96, 98]
Cerebral blood flow	0 8 liter per minute[115]
Extremities	1 8 liters per minute
Hepatic blood flow (including viscera drained by portal vein)	1 3 to 1 5 liters per minute[97, 131]

Diminished Cardiac Output

The cardiac output is less when the subject is upright than when he is recumbent probably due to the pooling of blood in the lower extremities and consequent diminished venous return to the heart in the former position [138, 140] The cardiac output is also diminished after prolonged standing on holding the breath in inspiration and in persons of advanced age Anxiety may be associated with an elevation in cardiac output [106]

Pathologic Conditions Associated with a Diminished Cardiac Output

1 Myxedema (p 1017)

2 Constrictive pericarditis (p 610) and occasionally pericarditis with effusion (p 594)

3 Paroxysmal tachycardia and atrial fibrillation with rapid ventricular rate—due to the diminished period of diastole and consequent reduction in diastolic filling (Chapter 14)

4 Heart block occasionally when the increased stroke output is insufficient to compensate for the slow cardiac rate (p 390)

5 Shock states (Chapter 12)

6 Valvular heart disease particularly aortic stenosis or mitral stenosis is often associated with a diminished cardiac output The cardiac output may be normal when the patient is at rest but increases less than normally with exercise The cardiac output may fail to increase with exercise

7 Congestive heart failure (This is discussed in detail in Chapter 8) Usually there is a decrease but the cardiac output may be normal With exercise there is little or no increase in cardiac output in contrast with the pronounced augmentation in normal individuals [104]

8 Atrial fibrillation Most observers have found the cardiac output diminished by 20 to 30 per cent with a corresponding increase when regular rhythm is reestablished by quinidine (p 359)

Increased Cardiac Output

The cardiac output is *increased* most commonly as a result of muscular exercise Digestion may increase the cardiac output by 30 to 40 per cent one hour after a meal and the increase may persist for three hours Emotional excitement may produce a similar increase The increase in cardiac output and consequent increase in the work of the heart may account for the precipitation of attacks of angina pectoris in susceptible patients following exercise meals or excitement The cardiac output is increased after the ingestion of fluids and after intravenous infusions in therapeutic doses Pregnancy is associated with an elevation of cardiac output varying between 30 and 50 per cent (p 1087) A rise in environmental temperature to above 30 C and the initial period of exposure to high altitudes are associated with increased cardiac output

Pathologic Conditions Associated with Increased Cardiac Output

1 Hyperthyroidism (p 1001)

2 Fever The increase as in Graves disease is due to the elevated metabolism The systolic output is unaltered or slightly diminished so that the increased cardiac output corresponds to the rise in heart rate

3 Anemia (p 1048)

4 Arteriovenous fistula (p 694)

5 Beriberi (p 1039)

6 Severe pulmonary emphysema (p 989)

7 Osteitis deformans

THE CIRCULATION TIME

The determination of the speed of blood flow is of clinical value because of its distinctive alteration in congestive heart failure and other circulatory disturbances Clinical

methods do not actually measure the velocity of the blood flow, which varies considerably in diverse parts of the vascular tree owing to differences in the caliber of arteries, capillaries and veins. The *circulation time* measures the shortest interval between the injection of a substance into a vein and its arrival at some distant site in sufficient concentration to produce a recognizable end point. It represents approximately the inverse of the average velocity of blood flow between two points.

The circulation time is related to both the cardiac output and the volume of the circulating blood. The circulation time tends to increase as the blood volume increases. The circulation time tends to diminish as the cardiac output increases, for the latter indicates that there is a greater volume of blood passing a given point in a given time. Unless the caliber of the vessel is enlarged, this is possible only if the speed of the circulation is increased. However, the circulation time may remain unchanged if there are simultaneous and similar increases in cardiac output and blood volume. This relationship may be expressed mathematically

$$CT = k\frac{BV}{CO}$$

in which CT represents the circulation time, BV the circulating blood volume, CO the cardiac output per minute and k a "constant" which however is undetermined and which in fact may vary somewhat in different individuals or even in the same individual under changing conditions. It is apparent from the above formula that the circulation time is most likely to be prolonged if there is both an increase in the blood volume and a diminution in cardiac output, findings typical of advanced congestive heart failure.

METHODS OF DETERMINING THE CIRCULATION TIME

The usual technique is to inject rapidly a foreign substance into a peripheral vein and to note the time elapsing between the injection and the arrival of the substance at some other point in the circulation. Koch[10] first employed fluorescein, but his method was impractical because of the need for multiple venipunctures. Fundamental work on the circulation time was contributed by Blumgart and Weiss.[4] They injected radium C into an antecubital vein and detected its arrival in the right side of the heart (arm-to-right heart time) and in the opposite antecubital artery (arm-to-arm time) by a special radiosensitive device.

Clinical Methods

The clinical methods which are used most generally measure the arm-to-tongue time and employ solutions of either Decholin, saccharin or calcium gluconate as the injected material. Volatile substances such as ether are often injected intravenously in order to determine the arm-to-lung time. These substances have the disadvantage of producing subjective end points. Consequently, the patient's reaction time and degree of cooperation are factors which may affect the result.

The test is performed with the patient recumbent after having rested at least twenty minutes. He should be reassured so that he is relaxed and his pulse and respiration are basal. In particular, he must be told not to hold his breath after insertion of the needle, as this may retard the venous return to the heart. The nature of the end point, such as a sweet or bitter taste, should be explained to the patient as well as the importance of his announcing it *immediately* by some agreed signal such as "now" or "sweet." After the tourniquet is applied and the needle inserted, the tourniquet should be released and 20 to 30 seconds allowed to elapse to permit reestablishment of the normal circulation in the vein before the injection is made. It is essential that the quantity of solution used be small enough and the bore of the needle large enough (about 18 gauge) to permit *rapid injection* (less than a second). A stop-watch is started at the instant the injection is begun and stopped when the patient signals the end point or when an objective end point is noted. Whenever possible the test should be repeated after a few minutes to check the result. Some of the substances most commonly used for the determination of the circulation time, their doses and end points are the following:

Decholin (sodium dehydrocholate)
- Quantity: Five cc. of a 20 per cent solution
- End point: Bitter taste and involuntary grimace
- Normal arm-to-tongue time: 10 to 16 seconds.[203]
- Comment: Sharp and usually reliable end point but relatively expensive. Occasional reaction.[182]

Saccharin (sodium benzosulfimide)
- Quantity: 2.5 cc. prepared by dissolving 2.5 gm. of soluble saccharin (Merck) in 2 cc. distilled water and heating *just enough* for solution

End point Sweet taste
Normal arm-to-tongue time 9 to 16 seconds[74]
Comment Cheap Small volume of solution needed Local venous thrombosis and painful swelling if perivenous tissue is infiltrated

Calcium gluconate
Quantity 3 to 5 cc of a 20 per solution
End point Hot sensation in tongue and pharynx
Normal arm-to-tongue time 10 to [illegible] seconds[84]

Magnesium sulfate
✓Quantity 10 cc of a 10 per cent solution (Also a mixture of magnesium sulfate and calcium gluconate has been used[194])
End point Hot sensation in tongue and pharynx
Normal arm-to-tongue time [illegible] to 17 seconds[17]

Fluorescein or Riboflavin
Quantity 2 cc of a 20 per cent or 3 cc of a 15 per cent solution of sodium fluorescein *or* 0 8 mg per kilo body weight of riboflavin[223]
End point Greenish yellow fluorescence in mucous membrane of lips or tongue[184] or in previously prepared histamine wheal of arm[312] Visualized in dark with source of ultraviolet light
Normal arm-to-lip time 10 to 16 seconds
Comment Objective end points

Alpha Lobeline
Quantity 0 5 cc of a 1 per cent solution
End point Cough usually with a grimace and hyperpnea[14]
Normal mean 11 to 12 seconds
Comment Unpleasant side actions

Sodium succinate
Quantity 1 5 cc of a 30 per cent aqueous solution of disodium succinate hexahydrate
End point Elevation of cricoid choking sensation cough
Normal arm-to-throat time 12 to 10 seconds (mean 15 8 sec)[8]

Radioactive Sodium
The circulation time may be determined by injecting radioactive sodium (Na^{24}) intravenously and clocking its arrival at any distant point by a Geiger Mueller counter[103]

Ether
✓ Quantity 5 minims ether and 10 minims normal saline[106] (1 4 cc paraldehyde may be substituted)[14]
End point Facial grimace cough ether taste or smell
Normal arm-to-lung time 4 to 8 seconds

Carbon Dioxide
Quantity Inhale 30 per cent mixture carbon dioxide in air[8]
End point Acceleration and deepening of respiration
Lung-to-carotid sinus time [illegible] to 10 seconds

Nitrogen or Helium
While the oximeter is measuring the arterial oxygen saturation in the ear the subject inhales a single breath of 100 per cent nitrogen or helium[69] The end point is a reduction in arterial oxygen saturation at the site of the oximeter This measures the lung-to-ear time[271]

Evans Blue (T 1824)
This has been used in diagnosis in congenital heart disease (p 759)

CLINICAL ABNORMALITIES OF THE CIRCULATION TIME

Diminished Circulation Time

The circulation time is *reduced* in the following pathologic conditions

1 Hyperthyroidism (p 1002)
2 Anemia (p 1017) The reduction in circulation time with both primary and secondary anemias parallels the severity of the anemia[203, 84]
3 Beriberi heart disease (p 1039)
4 Arteriovenous fistula (p 694)
5 Pregnancy (p 1088)
6 Congenital heart disease (p 797)
7 Febrile states Acceleration of the circulation is the result of peripheral vasodilatation

The circulation time is also reduced during digestion and after exercise Because of these effects *the circulation time should be determined when the patient is in a basal state*

Prolonged Circulation Time

A *prolongation* of the circulation time is observed in the following pathologic conditions

1 Congestive heart failure (p 107)
2 Polycythemia vera The slowing of the circulation[3] is dependent on the increase in circulating blood (erythrocyte) volume and the associated increase in viscosity of the blood
3 Myxedema (p 1018)

The circulation time is normal in cases of compensated valvular heart disease or hypertension *If the circulation time is prolonged in* these conditions careful investigation usually elicits some subjective or objective evidence of cardiac failure

DIAGNOSTIC VALUE OF THE CIRCULATION TIME

The chief use for the determination of the circulation time is in confirming the diagnosis of congestive heart failure By performing both an arm-to-tongue and arm-to-lung test and determining the venous pressure at the same time the cardiac failure may be attributed to the left or right side of the heart or both Prolongation of the arm-to-tongue (saccharin Decholin) time with a normal arm-to-lung (ether) time and a normal venous pressure usually denotes pure left-sided failure prolongation of both and elevation of the venous pressure indicate right-sided heart failure The simplicity of these tests which can

be readily performed both in the office and at the bedside makes them an integral part of the examination of the circulation

Often the circulation time helps to distinguish cardiac failure from a number of conditions which produce some of the same symptoms

1 **Asthma** In cases of bronchial asthma the circulation time is normal or it may be reduced Asthma due to heart failure is associated with a prolonged circulation time A normal circulation time usually excludes cardiac *failure* but not cardiac *disease*

2 **Dyspnea and Orthopnea** When dyspnea or orthopnea is due to intrinsic pulmonary disease without heart failure the circulation time is normal[16] But in cases of severe emphysema with diminished arterial oxygen saturation the circulation time may be diminished In cases of complete unilateral pneumothorax it may be rapid Dyspnea or orthopnea due to congestive heart failure is accompanied by a long circulation time

3 **Edema or Ascites** Edema due to nephritis nephrosis, postural defects or local venous disturbance and ascites due to cirrhosis of the liver or neoplasm, are associated with a normal circulation time In cases of anemia with edema there may be a normal or an abbreviated circulation time

4 **Hepatic Enlargement and Venous Engorgement** A determination of the circulation time may aid both in distinguishing hepatic enlargement due to heart failure from that due to intrinsic disease of the liver and in distinguishing the cervical venous engorgement of heart failure from that due to superior vena caval obstruction

The circulation time has been found of value in revealing obscure cases of hyperthyroidism This may be suspected when the circulation time is normal in an obvious case of congestive heart failure without associated severe anemia or avitaminosis The use of the circulation time measurements in the diagnosis of congenital heart disease is discussed on page 797

The circulation time is helpful in estimating the progress and prognosis of a patient with congestive heart failure As signs and symptoms of congestive heart failure regress the circulation time diminishes and may revert to normal It has been noted however, that the circulation time may increase although distressing dyspnea or orthopnea subsides when right sided heart failure is added to pure left-sided failure As a rule, a reduction in the long circulation time indicates improvement

VENOUS PRESSURE

Clinical measurement of the venous pressure is limited to the systemic (caval) venous branches However, an elevation of the pulmonic venous pressure can often be surmised when there are physical signs of congestion or edema of the lungs or roentgenologic evidences of pulmonary congestion in patients with cardiac disease

It is clinically desirable to determine the pressure in the systemic veins near their entrance into the right atrium As a rule the pressure in these great veins is not determined directly instead some more accessible vein nearby such as the external jugular vein or an antecubital vein is used To eliminate the factor of hydrostatic pressure the patient is examined in the supine position with the vein under consideration placed at the level of the right atrium This may not be a precise correction for there is some evidence that the zero reference point is not at the level of the base of the atria but some distance below[36] The mean right atrial pressure in normal subjects is -2 to $+2$ mm Hg relative to atmospheric pressure[22]

The measurement of the venous pressure can be made by clinical inspection, by indirect methods or by direct cannulation of a vein

Estimation of the Venous Pressure by Clinical Inspection

It was suggested by Gaertner[78] that when an extremity is elevated its veins represent a manometric column in communication with the right atrium The arm is elevated until a visible vein collapses At this point the venous pressure is just balanced by the hydrostatic pressure in the vein The height of the collapsed vein above the level of the atrium represents the venous pressure This method is useful only when the venous pressure is higher than normal The veins on the under-surface of the tongue have also been used to determine an elevation in venous pressure[11] Normally these are collapsed when the patient is sitting They become notably engorged when the venous pressure exceeds 20 cm of water

The use of the external jugular vein for estimating venous pressure has been emphasized by Lewis[123] Normally when the subject

sits or stands erect this vein fills to the root of the neck the height of filling increasing as the subject becomes more horizontal When the subject is recumbent the venous filling reaches a point which is on a horizontal level with the lower border of the manubrium sterni or the zero point of reference If the venous pressure is increased above normal the level of venous filling is correspondingly elevated Thus with congestive heart failure the jugular vein may be visibly filled for 2 or more cm above the level of the clavicle even when the patient is upright As the head and shoulders are lowered the height of venous filling increases and may reach to the angle of the jaw If the height of filling is not distinct gentle pressure over the lower end of the vein for a few minutes will accentuate the filling the pressure is then released and the vein observed again

Sometimes it is simpler to observe the jugular venous pulse The highest point to which this rises gives the level of venous filling and consequently measures the venous pressure When the superficial veins of an extremity are clearly visible e g, on the dorsum of the hand the venous pressure may be roughly estimated as the height to which the extremity must be elevated above the atrium in order to cause the vein to collapse

Indirect Method of Determining Venous Pressure

The indirect method[9] involves the determination of the external pressure necessary to cause a superficial vein to collapse this pressure being equal to the venous pressure A transparent, sometimes illuminated capsule with grooved edges is sealed with collodion over the vein to be studied Air is introduced into the capsule by an air pump or bulb until the vein collapses, while at the same time a connecting water manometer is observed for the exact pressure at which venous collapse is effected The system must be airtight The venous pressure can be determined in any position of the patient and the hydrostatic pressure may then be eliminated by subtracting the vertical height from the vein to the level of the manubrium sterni This method is too inaccurate for general clinical use

Direct Methods of Measuring Venous Pressure

Stephen Hales[98] first made direct measurements of the venous blood pressure by noting the height to which the blood rose in tubes inserted into the jugular vein of animals Present direct methods include that of Moritz and Tabora[149] or some modification such as that of Taylor Thomas and Schleiter[204] My experience is concerned chiefly with the latter method which I have found eminently satisfactory for practical bedside use The modification proposed by Griffith et al[93] or by Sodeman[193] has also been extensively used An aneroid type of manometer (phlebomanometer) was devised by Burch and Winsor[31]

Method of Moritz and Tabora[149] Insert into the median basilic vein a needle connected by adapter and tubing to a calibrated buret containing saline The saline and the apparatus must be sterile The saline is allowed to enter the vein until the inflow ceases At this point the level of the saline above that of the right atrium represents the venous pressure Moritz and Tabora[149] found the normal venous pressure to vary between 1 and 8 cm water and most frequently between 4 and 8 cm

Method of Taylor Thomas and Schleiter[204] A sterile L shaped calibrated glass tube 30 cm in length and of 4 mm bore is used the short limb being ground to fit an 18 gauge intravenous needle The tube or manometer is moistened with 5 per cent sodium citrate solution to inhibit coagulation The patient is supine with his upper extremity relaxed and abducted from the body at an angle of about 60 degrees This is to avoid compression or torsion of the axillary or subclavian vein when the arm is close to the body (If the patient is very orthopneic, the venous pressure may be determined with the patient seated, but the reference level for the zero mark should be the horizontal plane 4 cm below the fourth sternocostal junction [illegible]) The subject should rest at least 15 minutes before the procedure is begun A pillow or towel are placed under the arm to be used so that the antecubital vein is 5 cm below the horizontal plane of the anterior surface of the sternum at its fourth costochondral junction This represents approximately the level of the opening of the venae cavae into the right atrium The patient is instructed to relax and breathe naturally to avoid muscle [illegible] abnormal changes in intrathoracic pressure

A sphygmomanometer cuff applied [illegible] arm is inflated to 40 mm Hg or a tourniquet may be used The needle is inserted [illegible] into a large antecubital vein so as to [illegible] free flow of blood and the [illegible] pressure [illegible]

flated In the lower extremity the femoral vein may be used, the puncture being made upward and inward 2 5 cm distal to the inguinal ligament and just medial to the pulsating femoral artery The height of the column of blood, when it comes to rest in the tube, *represents the venous pressure* Consecutive readings should be made until they are constant The presence of a free communication with the blood stream is indicated by small excursions of the blood in the tube during respiration by a rise of the blood level in the tube when the cuff is inflated again and by a return to the previous level when deflated

It is apparent that because of gravity, the venous pressure is considerably higher especially in the lower extremity when the subject is standing than when he is recumbent To neutralize this hydrostatic effect the vein used for measuring pressure is kept at that level in the right atrium at which the pressure is zero This is known as the zero or reference level I have generally used a level of 5 cm below the horizontal level of a plane through the fourth costochondral junction, depending on the approximate thickness of the chest wall Lyons et al [138] have used a level 10 cm above the level of the skin of the subject's back when in the recumbent position and Hussey [113] the midaxillary line Winsor and Burch[224] have used a "phlebostatic level" which for the supine position is a horizontal plane half the distance from the base of the xiphoid to the table and *in the upright position* through the fourth intercostal space These *reference levels are equally valuable if consistency is maintained in all readings*

Aneroid Phlebomanometer of Burch and Winsor[31] This is an aneroid type of manometer calibrated in millimeters of water The pressure in the vein is balanced by the pressure in the manometric system which is attained by *mechanical compression of a* pressure bulb A glass adapter of 1 mm bore containing citrate solution connects the manometer to a 23 gauge needle which is inserted into an appropriate vein When the column of citrate solution balancing the venous blood pressure comes to rest the pressure is read from the scale of the manometer *The aneroid* manometer should be checked from time to *time* against a direct water manometer

Normal and Pathologic Venous Pressures

The normal venous pressure in an antecubital vein at the level of the right atrium is 4 to 8 cm water as determined by the direct method Greater variations have been noted by Moritz and Tabora[149] (1 to [illegible] cm), by Hussey [11] (4 to 12 cm) by Lyons et al [138] and Winsor and Burch[224] (5 to 14 cm) In my experience with the method of Taylor and his co workers [204] *the normal venous pressure* rarely exceeds 10 cm or falls as low as [illegible] cm water The venous pressure is the same in the upper and lower extremities when the veins are at the reference level of the heart [93, 224] The venous pressure in children is essentially identical with that in adults [126]

The venous pressure is increased by exercise, but usually returns to normal or lower *within a minute after its cessation* [201] With heart failure, the elevation is much greater and *it returns slowly to its previous level* [3] The venous pressure falls about 0 5 cm with quiet inspiration and rises to the same degree with normal expiration Cough and the Valsalva test increase the venous pressure The Muller experiment diminishes the venous pressure An infusion of 500 to 1500 cc of normal saline or of 5 per cent glucose solution may cause a significant increase in venous pressure only if more than 20 cc per minute is administered [49]

The venous pressure is elevated in the following *pathologic conditions*

1 *Right sided heart failure* Usually the venous pressure is between 10 and 20 cm , but it may rise as high as 30 cm or more Occasionally the venous pressure is only slightly elevated or even normal despite the presence of distinct hepatic enlargement and subcutaneous edema In such cases compresssion of the abdomen causes an elevation of venous pressure of 2 cm of water or more [178, 106] At the same time the jugular veins may become visibly engorged The more advanced the heart failure the higher the venous pressure *and the greater the elevation following* abdominal compression In normal subjects abdominal pressure causes no change or more often a slight fall in venous pressure in the upper extremity (p 154) [107] In some patients with mild or potential right heart failure the venous pressure may be normal at rest but abnormally elevated during exercise such as repeated flexion or elevation of the legs [201, 83, 3]

In pure left sided failure the systemic venous pressure is normal The venous pressure is often below 10 cm in patients with cardiac dyspnea and orthopnea and a prolonged

circulation time Presumably the pulmonary venous pressure is elevated (cardiac catheterization) Indirect evidence of elevated pulmonary venous pressure and venous engorgement are the prolonged circulation time and pronounced reduction in vital capacity In peripheral circulatory failure and in cardiac shock with strikingly diminished output the venous pressure is reduced to 3 cm or less In cases of acute coronary occlusion there is often a combination of shock and congestive heart failure the venous pressure depending on which factor predominates Sometimes in cases of shock the veins of the extremities are collapsed but the jugular veins are engorged and their pressure high

2 Constrictive pericarditis The venous pressure is extremely high usually above 20 cm Even slight abdominal compression causes a sharp rise so that the pressure exceeds 30 cm and the blood flows over the top of the tube

3 Pericardial effusions with cardiac tamponade

4 Thrombosis of the venae cavae

5 Mediastinal tumors aortic aneurysm etc [112]

6 Obstructive emphysema and bronchial asthma when associated with an increased intrapleural pressure and consequently with increased resistance to venous inflow [1, 2] The majority of patients with pulmonary emphysema have a normal venous pressure but in many cases an elevated venous pressure reflects increased intrapleural pressure

7 Local venous obstruction due to compression or thrombosis

Clinical Application of Determination of Venous Pressure

The chief value of determining the venous pressure is in the diagnosis and differential diagnosis of right sided congestive heart failure This diagnosis is usually indicated especially in a patient with known cardiac disease if the venous pressure is elevated or if it rises more than 1 cm after abdominal compression Other causes of elevated antecubital venous pressure can usually be excluded by roentgenologic examination of the chest with special reference to the lungs aorta and mediastinum Simultaneous determinations of the venous pressure and circulation time distinguish pure left-sided heart failure pure right sided heart failure and combined heart failure [114]

In right-sided heart failure the venous pressure is universally elevated Universal elevation of the venous pressure i e in the upper and lower halves of the body is also observed in cases of constrictive pericarditis and pericardial effusion with tamponade Obstruction to the superior vena cava by aortic aneurysm mediastinal or pulmonary masses or thrombosis produces an increased venous pressure only in the upper extremities Clinical inspection will also show venous engorgement limited to the upper part of the body Furthermore there is usually a visible collateral circulation in the anterior chest wall with a flow of blood from above downward Neither right-sided heart failure nor constrictive pericarditis produces sufficient venous obstruction to lead to the development of a visible collateral circulation I have seen a case of thrombosis of the superior and inferior venae cavae of unexplained etiology which caused a universal elevation of venous pressure but this generalized elevation of venous pressure could be distinguished from that due to heart failure because there was a visible collateral circulation in the chest wall

Obstruction to the venous return through the inferior vena cava produces an elevated venous pressure only in the lower extremities This may be observed with pregnancy abdominal tumors with and without ascites hypernephroma and other renal tumors invading the inferior vena cava hepatic tumors and thrombosis of the inferior vena cava [113]

A local venous obstruction e g in a subclavian vein will cause an elevation of venous pressure only in peripheral veins of the affected arm Obstruction due to an aneurysm of the aorta usually causes greater elevation in the left than in the right arm

In cases of constrictive pericarditis the venous pressure is extremely high and the elevation after abdominal compression is usually greater than in cases of right-sided heart failure secondary to left sided failure Furthermore the circulation time may be normal in contrast with the prolonged circulation time in the latter cases In cases of cardiac tamponade the high venous pressure is associated with a small pulse a low blood pressure and the clinical picture of shock

Comparative measurements of the venous pressure in the upper and lower extremities are of diagnostic value in distinguishing heart failure from superior vena caval obstruction

They also differentiate hepatic enlargement, edema and ascites due to right heart failure from similar findings due to other conditions [66] When enlargement of the liver is due to neoplasm or cirrhosis or when peripheral edema is due to nephritis avitaminosis, or local orthopedic or venous abnormalities in the legs without associated right sided heart failure the venous pressure in the arm veins is normal *The venous pressure in the lower extremities* may or may not be elevated

Repeated determinations of the venous pressure are valuable in the prognosis and treatment of right sided heart failure Improvement is frequently denoted by a progressive diminution of the venous pressure Conversely, a persistently high venous pressure despite rest in bed sodium restriction and the administration of digitalis and mercurial diuretics indicates a poor prognosis In cases of constrictive pericarditis these measures do not significantly reduce the venous pressure but effective surgical release of the heart is followed by a return of the venous pressure to normal

BLOOD VOLUME

The blood volume refers to the volume of the circulating blood Direct measurements *of the blood volume have been made by* exsanguinating animals or decapitated criminals By this means, the blood volume in humans was found to be one thirteenth of the body weight or between 5 and 6 liters For clinical purposes indirect methods must be utilized to determine the circulating blood volume [m] A known quantity of a foreign substance is introduced into the blood and its concentration in a sample of blood is determined some minutes later, when thorough mixing has occurred From these two values the blood volume can be calculated by dividing the quantity of injected material by its concentration in the blood at the time of uniform mixing The foreign substance must be non toxic in the quantity used must become evenly distributed in the blood, and must not diffuse out of the blood to any significant degree within the period of the test and its concentration in the blood must be readily determinable

One group of substances such as the dye Evans blue (T-1824) or radioiodinated plasma albumin are distributed throughout the plasma and are used to determine plasma volume Others, such as carbon monoxide radioactive P^{32} or radioactive chromium Cr^{51} are attached to and label only the erythrocytes and are used to determine red cell volume The blood volume is calculated from the determined plasma volume and hematocrit

$$\text{Blood Volume} = \frac{\text{Plasma Volume}}{100 - \text{Hematocrit}} \times 100$$

or the blood volume is calculated from the de termined red blood cell volume and the hematocrit

$$\text{Blood Volume} = \frac{\text{Red Blood Cell Vol}}{\text{Hematocrit}} \times 100$$

The blood volume may also be calculated by determining the plasma volume and the red cell volume individually and simultaneously with different test substances, and adding the two values

Determinations of total blood volume calculated from the hematocrit i e the relative erythrocyte volume $\left(\frac{\text{red cell volume} \times 100}{\text{total blood volume}}\right)$ measured by centrifuging blood from a large vein such as the antecubital, differ significantly from the more accurate total blood volume calculated from simultaneously determined plasma volume and red cell volume This is due to the fact that capillaries and small vessels contain less red cells and more plasma than large veins hence the over all cell volume per cent throughout the circulation is less than the venous cell volume per cent (venous hematocrit) [m, 87, 8, 87, 108] Trapping of plasma among the erythrocytes also tends to increase the measured venous hematocrit The ratio of the

$$\frac{\text{over all cell per cent (body hematocrit)}}{\text{venous cell per cent (venous hematocrit)}}$$

is fairly constant, namely 0 91 [35] Therefore the total blood volume tends to be underestimated when it is calculated from the red cell volume and venous hematocrit This must be considered in interpreting some of the recent reports of blood volume in congestive heart failure (p 166) If the $\frac{\text{total body hematocrit}}{\text{venous hematocrit}}$ is even lower than normal in congestive heart failure, as recently *reported* [108, 109] *the blood volume in* congestive failure would be especially underestimated in this condition when calculated from the red cell volume and venous hematocrit

DETERMINATION OF THE CIRCULATING BLOOD VOLUME

Evans Blue (T 1824)

This blue dye has been found preferable to the red colloidal dyes because its estimation is not impeded by similarity to the inherent color of plasma or by the occurrence of hemolysis The details of the method using Evans blue are reported by Gibson and Evans [illegible] and modifications have been described by others [80, 4, 170, 87, 49, 189]

Method The subject s height and weight are taken and his surface area calculated The determination should be made under basal conditions with the patient in the fasting state recumbent and resting at least twenty minutes

About 10 cc of blood is withdrawn without stasis into a dry centrifuge tube containing oxalate or heparin and the tube is inverted several times

Exactly 5 cc of a 0 5 per cent solution of Evans blue (T 1824) is injected intravenously

In 10 minutes exactly 10 cc of blood is withdrawn from another vein without stasis and added to a dry tube containing anticoagulant In cases of heart failure or shock this sample of blood is removed after 15 minutes because of the longer time required for uniform mixing of the dye

From the first tube enough blood is put into a Wintrobe tube and the hematocrit determined by centrifuging for 1 hour at 3000 R P M

The remainder of the dye free specimen as well as the specimen of blood containing dye is centrifuged

The dye free plasma is drawn off and read as a blank in the colorimeter and the plasma containing dye is likewise read in the colorimeter

From the prepared curve the plasma volume is calculated and the red cell volume and total volume determined from the hematocrit

For greater accuracy multiple specimens of blood should be taken at intervals of five ten fifteen and twenty minutes after injection of the dye and appropriate calculations made from the mixing curve obtained from the concentration values of the dye in these specimens A modification of the dye dilution method for serial estimation of plasma volume recently described by Plentl and Gelfand [169] is said to provide increased accuracy in administration of the dye and thus permit a reduction in the amount of dye used for each determination (3 to 4 mg instead of 15 to 20 mg)

The dye method has been criticized for yielding purportedly high values for plasma and blood volumes due to rapid passage of dye out of the blood stream into the lymphatics [illegible] However there is substantial evidence that this loss of dye is not significant during the test period and that T 1824 yields essentially reliable values for plasma volume [187, 188]

Radioactive Substances

The plasma volume may also be determined by the intravenous injection of serum albumin or plasma of which the albumin has been tagged with radioactive iodine I^{131}, [illegible, illegible, 13, 107] or with radioactive chromic chloride Cr^{51} [77]

The erythrocyte volume formerly determined by having the subject inhale carbon monoxide[44] or by injecting a donor s erythrocytes tagged with radioactive iron Fe^{59} by previously feeding the Fe^{59} to the donor [51] has more recently been measured by injecting erythrocytes more simply tagged in vitro with radioactive phosphorus P^{32} [164] radioactive chromium Cr^{51} as sodium chromate [88] or radioactive thorium B [103, 16] Various advantages have been noted for the use of radiochromium[88, 103, 174] and of thorium B[103] over previous methods employing radioiron or radiophosphorus

To avoid errors due to calculating the blood volume from the venous hematocrit the total blood volume has been measured by separate individual determination of the plasma volume and the erythrocyte volume This has been accomplished by simultaneous determination of the plasma volume with T 1824 or radioiodinated plasma albumin and of the erythrocytes by radiophosphorus[15] or radiochromium Plasma and erythrocyte volumes have also been determined simultaneously by using Cr^{51} as chromic chloride to determine plasma volume and as sodium chromate to determine red cell volume [87]

THE NORMAL CIRCULATING BLOOD VOLUME

The normal circulating plasma is approximately 4 to 4 5 per cent of body weight or 40 to 45 cc per kilogram This corresponds to a total blood volume of 70 to 80 cc /kg [80] The blood volume is about 10 per cent higher in

males than in *females*, chiefly owing to a greater red cell volume in males In obese persons the circulating blood volume is lower in relation to body weight than the average values stated, while in lean or emaciated persons it is higher The normal blood volume has a more constant value when related to surface area than to body weight But in persons who have undergone considerable changes in weight due to disease obesity or accumulation of edema the most accurate standards of blood volume are obtained when related to height

The reported values for plasma erythrocyte and total blood volumes vary according to the method employed The values for plasma volume determined by radioactive iodinated serum albumin and by T 1824 do not differ significantly [48, 137] But total blood volumes based on measured plasma volume and the hematocrit tend to be 10 to 20 per cent higher than those calculated from the measured red cell volume and hematocrit,[1] or from simultaneous individual determination of plasma volume and erythrocyte volume Thus Nachman et al [152] found an average plasma volume of 44 cc /kg with T 1824, an average erythrocyte volume of 29 cc /kg with radioactive phosphorus P^{32} and a total blood volume of 73 cc /kg But the total blood volume calculated from the T-1824 plasma volume and average venous hematocrit of 44 8 was 81 cc /kg and that calculated from the P^{32} erythrocyte volume and hematocrit was 65 cc /kg Simultaneous determinations of plasma volume by chromic chloride Cr^{51} and of erythrocyte volume by sodium chromate Cr^{51},[87] yielded values of 41 cc /kg for plasma 30 cc /kg for erythrocytes, and 71 cc /kg for total blood volume—values only slightly different from the values quoted above from Nachman et al [152] In terms of surface area the mean plasma volume is 1 5 liters per square meter the red cell volume 1 1 liters per square meter and the total blood volume 2 6 liters per square meter The blood volume in infants and children is much higher relative to body weight and surface area [181, 156]

The various methods of tagging erythrocytes with radioactive materials Fe^{59} P^{32} or Cr^{51} yield similar values The P^{32} technique has disclosed a mean erythrocyte volume of 30 cc /kg for males and 27 cc /kg for females [15] the radiochromium technique yielded a mean erythrocyte volume of 30 cc /kg [87] and thorium B, 30 to 35 cc /kg [182] Nomof and associates[159] noted that the erythrocyte volume as determined by carbon monoxide (34 cc /kg), was 16 per cent higher than by radiochromium (28 2 cc /kg)

In attempting to overcome the error due to calculating the total blood volume from erythrocyte volume and hematocrit the radioactivity after equilibrium has been measured in whole blood instead of in the centrifuged tagged red cells [190, 174, 16, 168] However, although the injected radioactive material may become uniformly distributed among the erythrocytes of the circulation, it is not uniformly distributed in the blood throughout the circulation since the relative red cell volume is less in capillaries and small vessels than in the large vessels from which blood is drawn for analysis[103] (p 220)

PHYSIOLOGIC AND PATHOLOGIC VARIATIONS IN BLOOD VOLUME

Increased Blood Volume

The circulating blood volume is *increased* with elevation of the environmental temperature with altitude during muscular exercise intense emotion and progressively during the latter half of pregnancy (p 1088) The blood volume increases temporarily following rapid transfusions and infusions or after the oral administration of large amounts of sodium salts [137]

The following *pathologic conditions* are also associated with an increase in blood volume which may be due essentially to an increased plasma volume, an increased cell volume or both

1 Polycythemia vera and secondary polycythemia (chiefly or exclusively red cell volume)

2 Leukemia (white blood cells and plasma)

3 Cirrhosis of the liver (plasma)

4 Splenomegalic anemias (plasma increased red cells diminished)

5 Hyperthyroidism (red cells and plasma—slight)

6 Cushing s syndrome (chiefly erythrocytes)

7 Congestive heart failure (p 166)

Diminished Blood Volume

The circulating blood volume is *reduced* on exposure to cold after sweating after prolonged abstinence from fluids, after anes

thesia and after standing erect for one-half hour or more It is also reduced by a low salt diet and by diuretic drugs such as the mercurials, acidifying salts or urea

The most important *pathologic conditions* associated with a reduction in the circulating blood volume are

1 Hemorrhage (plasma and cells)

2 Various forms of shock (see Chapter 12)

3 Diseases associated with severe diarrhea (plasma)

4 Diseases associated with persistent vomiting (plasma)

5 Myxedema (red cells and plasma—slight)

6 Chronic glomerulonephritis (red cells reduced plasma increased)

7 Severe pernicious anemia (red cells greatly reduced plasma increased slightly)

THE INTRATHORACIC BLOOD VOLUME

The intrathoracic blood volume has been regarded as an important factor in determining clinical manifestations in congestive heart failure particularly in cardiac disease associated with left sided heart failure The intrathoracic blood volume has been determined by the T 1824 dye method used to measure the cardiac output (p 210) The dye is injected intravenously or through a catheter in the pulmonary artery The blood between injection and sampling points termed the intrathoracic blood volume the central or the pulmonary blood volume may be calculated by multiplying the blood flow and the mean circulation time as determined from the dye concentration time curve [199, 148, illegible, 150, 131, 83, 117]

The normal resting pulmonary blood volume has been determined to be approximately 650 cc per square meter of body surface area or about 20 to 25 per cent of the total blood volume [illegible, illegible, 117] In conditions of generalized heart failure the intrathoracic blood volume may be greatly increased [26, 1 1, 83] Most of this increased blood may be stored in the enlarged cardiac chambers rather than in the pulmonary vessels [153, 77] There is disagreement as to the pulmonary blood volume in left heart failure,[1 5] Kattus et al [127] have reported normal or diminished central ' or pulmonary blood volume in patients with mitral and aortic stenosis and left sided heart failure On the other hand Borden and associates found the central blood volume increased in left ventricular failure but normal in mitral stenosis with pulmonary hypertension [illegible]

THE CIRCULATING BLOOD VOLUME IN CONGESTIVE HEART FAILURE (See p 166)

BODY WATER

Total Body Water

The general belief has been that *total body water* forms about 70 per cent of the body weight 50 per cent consisting of intracellular fluid and 20 per cent of extracellular fluid More recent determinations by the dilution of deuterium oxide (heavy water)[184] and of antipyrine[19, illegible] and N acetyl 4 amino antipyrine[11] have shown that total body water averages about 55 per cent in males and somewhat less in females [illegible] With improved methods for assaying tritium (radioactive hydrogen H^3) by means of the ionization chamber or proportional counter tritium labeled water has also been used to determine body water and has yielded results essentially similar to that obtained with deuterium and 2 to 4 per cent higher than that obtained with antipyrine [171] In edematous patients the antipyrine space has been found to be about 15 per cent smaller than the deuterium space [111] In normal persons two to four hours are required for complete mixing But in congestive heart failure and other edematous states and especially in the presence of serous effusions five to nine hours or longer may be necessary and the results are less reliable The dilution methods using radioactive materials as test substances are most accurate but involve formidable techniques Antipyrine has been found most satisfactory for clinical use but serial samples of blood are required because of its relatively rapid disappearance from the blood

The percentage of body weight due to water varies considerably with variations in body fat Determinations on the basis of desiccation studies[146] and specific gravity indicate that the body water forms a more constant percentage of lean body mass i e body weight exclusive of adipose tissue namely about 70 to 73 per cent [277, 10]

$$\% \text{ Body water} = 0.73\,(100\% - \%\text{ body fat})$$

Body fat may be determined from the whole body specific gravity[173] by the following formula

$$\% \text{ Fat} = 100 \times \frac{5.548}{\text{Sp. Gravity}} - 5.044$$

The significance of total body water in various states would be greatly enhanced if there were a simple method of assessing body fat and thereby of determining body water in terms of lean body mass

Extracellular Fluid Volume

The term *extracellular fluid volume* requires careful definition when discussed in terms of the substances used to measure it The extracellular fluid includes the plasma and the ultrafiltrate of plasma bounded by capillary and cell membranes This properly includes the extracellular fluid of bone and tendon, which has special features Many of the substances employed to determine extracellular fluid enter cells, tendon or bone to a variable extent and therefore measure a space of distribution of their own which is variably larger than the extracellular fluid volume as defined above There is no general agreement as to the inclusion of cerebrospinal fluid and gastrointestinal fluid (transcellular fluid) in the extracellular fluid

The extracellular volume has been measured by injecting known amounts of substances which are thought to mix uniformly throughout the extracellular fluid The extracellular fluid is calculated as the quantity of substance introduced intravenously divided by the concentration in the plasma at the time of complete uniform mixing Smaller spaces approximately 15 to 20 per cent of body weight, have been determined by the use of inulin[1,4,79,188] sucrose[61] mannitol[illegible] thiosulfate[33] *and radiosulfate*[illegible] *than by thio*cyanate[45] [illegible] bromide[illegible] radioactive chloride[05] or sodium Na[4,21] which yield spaces approximately 20 to 30 per cent of body weight

Studies by Swan and associates[200] of the extracellular volume in nephrectomized dogs indicated that the radiosulfate thiosulfate and mannitol volumes were apparently equal when measured simultaneously in the same animal, whereas the volumes of distribution of *inulin* and *sucrose* were somewhat smaller On the basis of simultaneous studies of the distribution of inulin and thiosulfate in tissues, and their correlation with chloride and connective tissue content of tissues in dogs Nichols and associates[157] found evidence indicating that the extracellular fluid consists of two phases (1) a smaller physiologically active space measured by inulin, and (2) a larger or total extracellular phase which includes also connective tissue extracellular *fluid, measured by substances such as chlo*ride The lowest extracellular volumes, measured by inulin, result from slow and incomplete penetration of connective tissue such as tendon Slightly higher values are afforded by substances such as thiosulfate, which penetrate connective tissue more readily or are destroyed in the body during the test period The largest "extracellular volumes" are afforded by chloride thiocyanate or sodium because they penetrate connective tissue more rapidly, because sodium in particular penetrates bone and because all three enter the intracellular space to a variable extent[140]

The imperfections in determining the extracellular fluid in normal subjects are increased in the presence of heart failure with edema and serous effusions chiefly because of the longer period required to obtain uniform mixing[illegible] Direct measurements made by the above methods as well as balance studies indicate that the extracellular fluid volume in *heart failure is two to three times the normal,* amounting to 35 to 60 per cent of body weight[1,2,216]

Intracellular Fluid Volume

Intracellular fluid is calculated as the difference between total body fluid measured as the antipyrine or deuterium space, and the extracellular fluid measured as the inulin sucrose thiosulfate or thiocyanate space[illegible] This indirect method of calculation is limited in accuracy by the imperfections in determin*ing total and extracellular body water Simul*taneous measurements by antipyrine and sucrose have indicated that the intracellular water averaged 40 per cent of body weight[197,12]

EXTRACELLULAR AND INTRACELLULAR ELECTROLYTES

This subject has been discussed in part in relation to congestive heart failure (p 168)

Extracellular Sodium and Potassium

The determination of plasma sodium and plasma potassium has been greatly facilitated by the development of the flame photometer[97] Small samples of plasma (0.5 ml), diluted 200 times for sodium and 50 times for potassium are poured into a funnel type atomizer and vaporized under constant air pressure into a flame supplied by gas under constant

exchangeable sodium, during the period of equilibrium of injected Na^{24} [59] The importance of bone sodium is indicated by evidence that about 30 per cent of body sodium is in bone (p 170)

Chlorides

The chloride concentration in plasma or urine is determined by standard chemical methods such as the modification of Sendroy's iodometric titration method[97] or that of Schales and Schales[183] Since injected bromide distributes itself throughout the body in proportion to the quantity of chloride in the body the extent of bromide dilution is used as an approximate measure of *total body chloride*[218, 65] The total body chloride is calculated by multiplying the bromide space $\left(\frac{\text{retained bromide}}{\text{plasma bromide conc}}\right)$ and the plasma chloride concentration The "chloride space" and total exchangeable chloride have also been determined by the use of radiochloride Cl^{38} [95] in a manner similar to that described for Na^{24} Intracellular chloride may be calculated by subtracting extracellular chloride (inulin or sucrose extracellular space multiplied by plasma chloride concentration) from total body chloride Then intracellular chloride concentration is determined from intracellular chloride and intracellular body water

The plasma concentration of chloride is approximately 103 milliequivalents per liter (range 90 to 110) Total body chloride averages 30 milliequivalents per kg body weight[65] *Intracellular chloride averages 25 milliequivalents per liter of intracellular fluid* This is

$$pH = pK + \log \frac{BHCO_3}{H_2CO_3} = pK + \log \frac{CO_2 - 0.1316\ \alpha\ p}{0.1316\ \alpha\ p}$$

$$= 6.10 + \frac{\log CO_2 - 0.067p}{067p}$$

substantially less than the intracellular concentration of sodium (40 mEq/L) determined by isotopic dilution There is also an excess of bone sodium over bone chloride The relatively high intracellular concentration of chloride indicates that the volume of *distribution of chloride is not an accurate* measure of the extracellular fluid

BLOOD pH AND BLOOD GASES

Studies of the blood pH, carbon dioxide and oxygen are often useful or essential in the understanding of electrolyte and hypoxic aberrations in heart failure in congenital heart disease and especially in heart disease associated with pulmonary or renal insufficiency Determinations of arterial and mixed venous oxygen concentrations are used in determining the cardiac output by the direct Fick method

Blood pH

The pH of the blood is not infrequently modified in cardiac patients with heart failure by therapeutic agents or by complicating or associated pulmonary, renal or metabolic disease The pH of plasma and of whole blood are the same The pH of the blood may be determined electrometrically, using a *Cambridge pH meter with a closed glass electrode*[139] If pH readings are not made at 37° C, a temperature correction must be made[179] In all blood gas and pH determinations the blood must be drawn without stasis and handled under anaerobic precautions to prevent loss of carbon dioxide or access of oxygen *Lactic acid formation by glycolysis must* be minimized by the use of fluoride and prompt analysis

The plasma or blood pH may also be determined colorimetrically by using Hastings and Sendroy's modification[102] of Cullen's method[47] *The whole blood or plasma is* diluted with phenol red indicator in saline and compared with standard solutions of known pH containing the same indicator

The plasma pH may be calculated from the carbon dioxide content of plasma (CO_2) the carbon dioxide tension (p) and the carbon dioxide solubility α by means of the Henderson Hasselbalch equation[210]

if CO_2 content is expressed as volumes per cent In practice the carbon dioxide content is determined and the pH of the plasma can be read directly from carbon dioxide absorption curves with plasma carbon dioxide contents interpolated on them[61, 168]

The mean pH of normal arterial blood or plasma is approximately 7 40 with a range of 7 34 to 7 43 The pH of venous blood is somewhat lower approximately 7 37, with a usual range between 7 32 and 7 41 In heart failure the arterial blood pH is usually normal or slightly elevated[7] the latter owing to alka

losis caused by hyperventilation The venous blood pH is usually normal in heart failure [191]

Acidosis, with reduction in blood pH, may occur in heart failure when there is associated renal insufficiency or carbon dioxide retention due to pulmonary insufficiency or a low plasma sodium or ammonium chloride toxicity (p 284) Alkalosis with elevated pH may occur as a result of hyperventilation of heart failure itself or associated pulmonary fibrosis with alveolar-capillary block or following vigorous mercurial diuresis

Table 6 pH Carbon Dioxide and Oxygen in Arterial and Venous Blood and Plasma

	ARTERIAL		VENOUS	
	Whole Blood	Plasma	Whole Blood	Plasma
CO_2 content m mol/l	21–22	25–27	22–24	26–28
CO_2 tension mm Hg	38–41	38–41	44–48	44–48
pH	7 40	7 40	7 37	7 37
O_2 saturation %	96–98	96 98	65–75	65–75
O_2 tension mm. Hg	95–105	95–105	33–40	33–40

Carbon Dioxide Content and Tension

Total carbon dioxide in blood includes that present as bicarbonate and that in carbonic acid The carbon dioxide content of plasma or whole blood may be determined by the method of Van Slyke and Neill [208, 168] using the manometric Van Slyke apparatus or by the gasometric method of Scholander et al [183] But this involves some difficulty in the prompt and careful anaerobic separation and handling of the plasma The *whole blood carbon dioxide content* may be measured by the manometer or in the Roughton-Scholander syringe by the combined method for carbon dioxide and oxygen [208, 183]

In normal blood the plasma carbon dioxide content is about 1 [illegible] times the carbon dioxide content of red blood cells Therefore the carbon dioxide content of plasma is higher than that of whole blood If plasma cannot be separated anaerobically the plasma carbon dioxide can be determined from line charts based on measurements of the total blood carbon dioxide oxygen capacity and pH [209]

The carbon dioxide content of arterial whole blood is approximately 21 to 22 millimols per liter, that of arterial plasma 25 to 27 millimols per liter that of venous whole blood 22 to 24 millimols per liter, that of venous plasma 26 to 28 millimols per liter

The *carbon dioxide tension* may be calculated from line charts if the carbon dioxide content oxygen capacity and pH of blood have been first determined [167] For direct determination of blood carbon dioxide tension whole blood at 37 C is equilibrated with a bubble of gas at atmospheric pressure whereby the bubble attains the same carbon dioxide tension as blood This final carbon dioxide tension of the bubble (and therefore of the blood) is determined by micro gas analysis of the bubble with the Van Slyke apparatus [210] or in the capillary portion of the same Roughton-Scholander syringe in which equilibration was effected [175, 127, 68] The *normal carbon dioxide tension* of arterial blood is approximately 40 mm Hg (usually 38 to 41 mm), and of venous blood usually 44 to 48 mm Hg The carbon dioxide tension of plasma is the same as that of whole blood The carbon dioxide content and tension of arterial whole blood are usually normal or slightly lowered in heart failure [74, 180] The venous blood carbon dioxide tension is usually normal in heart failure [180]

Oxygen in the Blood

The *oxygen content of blood* is determined by the method of Van Slyke and Neill [208] by use of Van Slyke s manometric apparatus or by the microgasometric method of Scholander et al [183] The oxygen and carbon dioxide content of whole blood can be measured simultaneously on the same specimen Arterial or arterialized blood is used This must be collected carefully without stasis or bubbles without exposure to air into a syringe rinsed with heparin as an anticoagulant and fluoride to minimize glycolysis The syringe is tightly capped and placed in a container of ice and water except when samples are removed for analysis When mixed venous blood is to be analyzed as in determining the cardiac output (p 210) it is obtained by cardiac catheterization from the pulmonary artery or right ventricle

The *oxygen capacity* is determined by first saturating the blood with air by rotating it in a separatory funnel to convert all the reduced hemoglobin to oxyhemoglobin

The oxygen saturation per cent is calculated

from the oxygen content and oxygen capacity

$$\% \text{ oxygen saturation} = \frac{\text{oxygen content}}{\text{oxygen capacity}} \times 100$$

The oxygen capacity and oxygen content, as usually determined by gasometric methods include oxygen dissolved in plasma as well as oxygen in oxyhemoglobin Therefore, to determine oxygen saturation from the content and capacity it is necessary to subtract 0 2 to 0 3 volume per cent of dissolved oxygen from the measured oxygen content and 0 5 to 0 7 volume per cent from the measured capacity the exact value varying according to the barometric pressure and room temperature of the air used to saturate the drawn blood with oxygen

Methods have been devised for more direct determination of oxygen saturation [12] to permit more rapid or continuous measurements These include the use of filter photometers (oximeters[41]) which may be attached to the warmed ear or which measure the oxygen saturation of arterial blood diverted into polythene tubing Since oxyhemoglobin absorbs less visible red light (wave length 620 to 770 millimicrons) than does reduced hemoglobin varying percentages of oxyhemoglobin and reduced hemoglobin alter the amount of light absorption and thereby the intensity of the current of the photocells in the oximeter In some oximeters the galvanometer must be preset and relative changes in oxygen saturation are recorded in others *absolute* oxygen saturations may be recorded without presetting [2,6] but the oximeter must first be calibrated against known arterial oxygen saturations Oxygen saturation of blood may be determined accurately also on undiluted, unexposed blood by direct measurement in a polarization spectrophotometer [54]

The *normal oxygen capacity* of blood varies with the total hemoglobin content Since 1 gm of hemoglobin can combine with 1 34 volumes of oxygen, blood with a total hemoglobin of 15 gm per 100 ml has an oxygen capacity of 20 volumes per cent The *normal oxygen saturation* of arterial blood is usually 96 to 98 per cent i e 96 to 98 per cent of the total hemoglobin is in the form of oxyhemoglobin

The oxygen saturation of peripheral venous blood is very variable (25 to 90 per cent) depending on blood flow and local metabolism Mixed venous blood obtained preferably from the pulmonary artery, usually contains 4 to 5 5 volumes per cent less oxygen than arterial blood, its oxygen saturation is usually 65 to 75 per cent

The *arterial oxygen tension* (pO_2) rather than its oxygen content or saturation is the factor determining the supply of oxygen to tissues and the transfer of oxygen from pulmonary alveoli to pulmonary capillaries

The oxygen saturation of hemoglobin at a constant temperature and pH is determined by the oxygen tension to which blood is exposed By plotting oxygen tensions along the abscissa and percentage of oxygen saturation on the ordinate an oxyhemoglobin dissociation curve is constructed for a given pH (Fig 56) Thus the oxygen tension of arterial blood can be read off this curve if the pH and the per cent oxygen saturation have been determined [40] The normal arterial oxygen tension is 95 to 105 mm Hg at sea level

The nature of the curve is such that reliable oxygen tension values are obtained for oxygen saturations between 10 and 70 per cent where the curve is virtually linear Above 70 per cent oxygen saturation the curve tends to level off and then flattens to such a degree that slight changes in oxygen saturation correspond to relatively large changes in oxygen tension A fall from 98 to 95 per cent arterial oxygen saturation corresponds to a fall of pO from about 100 to 80 mm Hg and at 90 per cent oxygen saturation the oxygen tension of arterial blood at pH 7 4 is approximately 60 mm Hg Hence slight errors in the determination of oxygen saturation in its higher ranges may result in significant errors in pO_2 when the latter is calculated from the oxyhemoglobin dissociation curve

The nature of the dissociation curve in the higher ranges of oxygen saturation is important in the interpretation of even slight reductions on oxygen saturations found in some cases of heart failure or pulmonary disease Thus an arterial oxygen saturation of 93 per cent sometimes regarded as virtually normal actually represents only 70 to 75 mm Hg oxygen tension instead of the normal of about 100 mm Hg

For more accurate determinations of arterial oxygen tension, the blood sample is equilibrated by thorough mixing with a small bubble of a gas in a closed tonometer or

syringe[175, 84] The gas bubble attains the same tension as the gas tension of the blood. The oxygen content of the bubble is determined by the Van Slyke manometric apparatus or in the Roughton-Scholander syringe in which equilibration of the blood and gas bubble is performed. The final oxygen tension of the bubble is calculated from its oxygen content and this tension is presumed to be identical with the oxygen tension in the drawn blood. Accuracy in this difficult method depends on avoidance of errors in blood sampling, in metabolism of the blood, and in analytic technique.[33, 83]

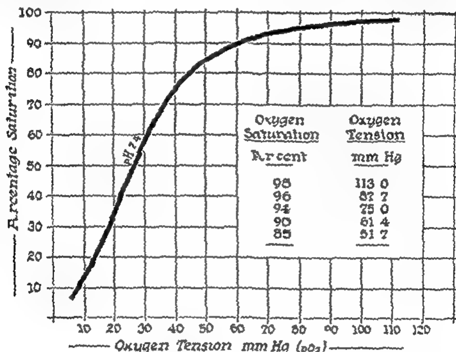

Fig. 56. Oxygen dissociation curve—human blood.

Another method particularly applicable to oxygen tensions in the high range (above 150 mm Hg) depends on measurements of the concentration of physically dissolved oxygen made on plasma separated anaerobically from erythrocytes. These measurements may be made by gasometric analysis or by polarography.[10]

TEST OF PULMONARY FUNCTION (see p. 971)

TESTS OF MYOCARDIAL RESERVE

In most cases of cardiac *disease* without failure, tests of circulatory *function* may all yield normal results. This merely indicates that the circulatory compensations for the disease are adequate to maintain a normal circulation when the patient is at rest or performing his ordinary activities. Additional tests have been designed to determine the adequacy of the circulatory response when some special strain is placed on the circulatory system. These are really attempts to test the myocardial reserve (p. 87).

Tests of myocardial reserve[150, 13, 1, 68] usually note the effect on the pulse rate, the blood pressure or the respiratory rate after the patient performs some procedure which strains the circulation. Most often this strain is effected by some form of physical exercise, but breath holding, the Valsalva procedure, immersion in warm bath, and others have also been employed. In addition to observing the effect on the pulse, blood pressure or respiration, one may also study the effect on the electrocardiogram, the size of the heart or the consumption of oxygen.[161]

A commonly used simple test consists of recording the pulse rate before and after the subject changes from the sitting to the standing position, after 10 knee bendings or after hopping 50 times on one foot. If the original pulse rate is 80 per minute, the increase in

rate should not exceed 10 on standing 20 after knee bending or 30 after hopping In each of the tests the pulse rate should return to the original level within two minutes As a result of the test the blood pressure should not rise more than 10 mm Hg and should return to the initial level within two minutes The respiratory rate should not increase more than 6 per minute Messinger[143] has stressed the value of observing the ratio of the pulse rate to the respiratory rate In normal subjects this ratio increases with exercise in patients with cardiac disease it does not increase Thus the ratio after an exercise test in normal persons was found to be 5 5 but in cardiac patients it was less than 4 5

Efforts have been made to standardize these exercise tests so that a fixed amount of exercise is performed in a given time, the amount depending on the age sex and weight of the subjects Such a standardized exercise tolerance test involving a variable number of ascents of two steps each 9 inches high, in a period of one and a half minutes was described by Master and Enid Oppenheimer[141] The number of climbs for each subject is determined from tables In normal persons *the pulse rate does not rise more than 10 beats* per second and the blood pressure not more than 10 mm Hg Both return to the initial level in two minutes

The clinical history is often a better guide to the patient s response to exercise than any of the utilized objective tests The amount of activity required to produce dyspnea and any change in the ability to perform usual activities without dyspnea are often revealing as to the maintenance or reduction of normal cardiac function Due care is required in the interpretation of dyspnea and its differentiation from sighing respiration The possible role of pulmonary disease obstructive diseases of the respiratory tract recent excessive weight gain and obesity requires careful study

A variety of other tests of myocardial reserve have been described One of the simplest is the *breath holding test* The normal person can hold his breath for 30 seconds or longer Subjects with limited cardiac reserve cannot usually do this for more than 20 seconds The same test may be performed immediately after some exertion such as 10 knee bendings After such exercise the patient with diminished cardiac reserve cannot usually hold his breath for more than 12 seconds A modification of this test consists in observation of changes in the pulse and blood pressure while the subject is blowing through a tube against a fixed pressure A clinical instrument of this type, termed the Flanmeter, has been used to test circulatory fitness[210] The *Schellong test* requires a subject to stand for ten to twenty minutes during which time continuous measurements of his blood pressure are recorded Poor circulatory function is denoted by a fall of the systolic blood pressure of 20 mm Hg or more The subject may collapse if the fall in pressure is excessive especially if he suffers from postural hypotension

During the *Valsalva test*, the heart in normal persons becomes smaller, as observed by fluoroscopy In patients with poor myocardial reserve it may dilate Electrocardiographic studies following exercise have also been utilized to demonstrate poor myocardial or coronary circulatory reserve (p 469) Similar electrocardiographic changes are produced by breathing procedures associated with anoxemia (Chapter 18)

Nylin[161] utilized the determination of the oxygen debt after exercise as the basis of a test of circulatory function After a standard exercise which consists of stair climbing Nylin observed that the increase in oxygen consumption after cessation of exercise (i e the oxygen debt) is much greater in subjects with diseased hearts than in normal persons A diminished capacity in cardiac patients for increasing the cardiac output during exercise is the basis of a cardiac function test utilized by Neukirch[155] A diminished capacity of cardiac patients to increase oxygen consumption during a standard strenuous exercise test may also be used as a test Szostrand and Wahlund[92] determined the rate of work on a bicycle ergometer which caused a rise in pulse rate to 170 per minute In cardiac patients this occurred at relatively low work intensities

The various tests of circulatory function or myocardial reserve are of very limited value The responses of pulse and blood pressure to stresses are too variable to be employed as a diagnostic test and there is considerable overlapping of the findings in normals and cardiac patients Most important the response to these stresses frequently depends on emotional factors and training and may be modified also by pulmonary metabolic, muscular or cerebral disease as well as by cardiac disease

Chapter 11

THE TREATMENT OF CONGESTIVE HEART FAILURE

Treatment of the Underlying Causes of Heart Failure

In order to treat congestive heart failure most effectively it is desirable to determine the etiologic factors responsible for its development. In many cases, e.g. those due to coronary artery disease, no specific treatment can be applied to the etiologic factor. In other cases of congestive heart failure, the major element in treatment is the cure or alleviation of the underlying cause. Thus thyroidectomy or antithyroid medication in cases of heart failure due to Graves' disease, decortication of the heart in those due to constrictive pericarditis, and closure of the fistula in those due to an arteriovenous aneurysm are often life saving measures without which treatment of heart failure per se is futile. Similarly specific medical treatment of vitamin B deficiency, hypothyroidism, anemia or diphtheria toxemia may be curative in cases of heart failure associated with beriberi heart disease, myxedema heart, chronic or acute hemorrhage or diphtheria respectively. Repair of a patent ductus arteriosus, coarctation of the aorta, or of other congenital cardiovascular defects may dispel heart failure.

When cardiac failure appears early during pregnancy, a therapeutic abortion may be necessary to alleviate the symptoms. When cardiac failure is precipitated suddenly by extreme tachycardia such as may accompany a paroxysm of atrial fibrillation, treatment consists of prompt slowing of the heart by digitalis, strophanthin or quinidine. Heart failure with pulmonary edema precipitated by a hypertensive crisis may be controlled by parenteral administration of a hypotensive drug such as protoveratrin. Mild antiluetic therapy directed against the primary cause of failure associated with syphilitic heart disease gives less striking results than in the conditions mentioned above but it may prolong life.

Preventive Measures

The prevention of cardiac failure in patients with known heart disease is pertinent. Respiratory infections should be avoided, especially in patients with rheumatic heart disease. The prophylactic and therapeutic use of antibiotics to control infections is of special value in cardiac patients. Limitation of emotional strain and physical exertion may be important in patients with hypertensive or coronary heart disease. Chronic cough should be controlled by rest, codeine, etc., as the associated strain may precipitate cardiac failure. Lesions associated with recurrent bleeding and anemia, e.g. peptic ulcer or bleeding hemorrhoids should be cured medically or surgically, especially in patients who already suffer from an insufficient coronary blood supply. The rapid or excessive intravenous administration of fluids may induce congestive heart failure and should be avoided. The adequate specific treatment of syphilis in patients with early cardiovascular syphilis will prevent or postpone the development of heart failure. Similarly control of hyperthyroidism should be effected before cardiac failure develops. Dietary control of obesity, particularly in middle-aged or elderly cardiac patients may diminish the probability of heart failure.

Prophylactic periods of bed rest are desirable for patients who have previously suffered attacks of failure. Careful maintenance of digitalization, low sodium intake and other prescribed medication are often essential to avoid recurrence of heart failure after the initial attack is controlled. Avoidance of prolonged or exaggerated bed rest and the use of anticoagulants in cardiac patients requiring bed rest may diminish the probability

of thromboembolic complications and their precipitation of heart failure

GENERAL THERAPEUTIC MEASURES

Principles of Treatment

In addition to the elimination or control of the precipitating or contributory factors treatment consists essentially of the following

1 *Improvement in cardiac efficiency* This is effected by (a) limitation of physical activity which reduces the load on the heart and (b) digitalis administration which improves cardiac function probably by direct action on the heart

2 *Control of sodium water retention* This involves a sharp limitation of sodium intake and the use of diuretics especially mercurial diuretics which promote the excretion of sodium and water through the kidneys

These and other secondary therapeutic measures will be discussed individually in the following pages However in execution most of these therapeutic measures are utilized simultaneously To obtain maximal effects as soon as possible Gold Kwit et al[148] have recommended a five pronged program including (a) rest in bed or chair (b) extreme sodium restriction (c) daily mercurial diuretics (d) single dose rapid digitalization and (e) daily weighing as a guide to the removal of extracellular fluid (edema) The program is continued until all gross signs of edema disappear and the body weight reaches a minimal and basic level Attractive as their routinized program appears great caution and judgment are essential in its application to individual patients There is danger in the simplicity of dogmatic therapeutic instructions In particular digitalis dosage and the frequency with which mercurial diuretics are administered require considerable elasticity

It is equally important to maintain therapeutic control after the manifestations of congestive heart failure have been abolished Activity is limited but liberalized according to tolerance Digitalization is maintained Sodium restriction and the administration of mercurials are continued according to the patient s weight and clinical symptoms The optimum regime should be maintained as the diabetic s regime is maintained It is as faulty to discontinue treatment until heart failure recurs as to restrict diet and administer insulin to the diabetic only when he develops diabetic acidosis However occasionally when heart failure is precipitated by an acute infection or the sudden development of severe anemia compensation is readily established by control of infection or anemia and may be maintained without continuing digitalis diuretics or a strict low sodium diet

REST

The Rationale of Rest

Rest is designed to alleviate heart failure by diminishing the work of the heart Heart failure denotes an inability to maintain an output adequate for the needs of the body Those needs can be minimized by eliminating physical exertion Hickam and Cargill[179] showed that the patient in heart failure is unable to meet the stress of exercise with an increase in cardiac output as the normal individual does Merrill and Cargill[81] found that the renal blood flow in patients with moderate heart failure may be normal with the patient at rest but inadequate with exercise And Landis et al[85] observed in experimental heart failure that the venous pressures which were normal with the animal at rest became elevated during exercise These abnormalities of renal blood flow and of venous pressure induced by activity have been related to some of the basic disturbances in heart failure (sodium water retention and edema) Activity promotes the venous return and produces pulmonary congestion and dyspnea when the left side of the heart is incompetent The purpose of bed rest is to avoid these circulatory handicaps imposed by activity

Rest reduces the work of the heart also by diminishing the blood pressure thus permitting the heart to contract against a lower resistance By eliminating dyspnea rest decreases the work of the respiratory muscles the oxygen utilization and the work of the heart By slowing the cardiac rate it prolongs the diastolic period of recovery and results in improved efficiency of cardiac contraction The final proof of the value of rest is the rapid alleviation of dyspnea and other symptoms which the patient often discovers for himself Often especially when the symptoms of failure are relatively mild and of brief duration rest alone effects a cure This was strikingly indicated by Fothergill[7] in 1872

In recent years attention has been directed repeatedly to the dangers of bed rest[164, 77, 210] These admonitions should not be misin

terpreted The physician must distinguish between essential bed rest and unnecessarily prolonged bed rest, between the judicious use and the excessive abuse of rest A distinction should be drawn also between rest and recumbency For patients with congestive heart failure may obtain the desired rest, with more comfort propped up in a large chair or bed than when at complete rest in the horizontal position If bed rest is desirable 8 to 10 inch blocks may be placed under the head posts to relieve orthopnea

The greatest danger of bed rest in patients with heart failure is the invitation to phlebothrombosis and pulmonary embolism Deep breathing and leg exercises changes in position and the use of anticoagulants are measures designed to overcome these dangers (p 572) The hazard of bronchopulmonary infections always lurking in patients with bronchial or pulmonary stasis due to congestive heart failure, is enhanced by inactivity in bed especially in the obese the indolent and the elderly The restricted judicious use of sedatives and narcotics will minimize the danger of complete immobility of the patient Exaggerated straining at stool in using a bed pan often enhances the danger of fatal pulmonary embolism

Elderly patients often become completely bedridden with prolonged bed rest Osteoporosis bone atrophy and muscle wasting become intensified Urinary retention may be precipitated in patients with prostatism Constipation, cathartic habituation, back strain bed sores and psychoneurosis are among the other hazards attributed to complete and prolonged bed rest

Duration of the Rest Period in Bed

Rest may involve a complete stay in bed for a continuous period, confinement during occasional days of the week or hours of the day or various modifications of these, or it may merely consist of a limitation of activity at work or at home These are discussed below

According to its severity, heart failure may require the patient to remain in bed for periods of one to four weeks or longer Usually in uncomplicated cases of moderate severity, proper treatment combined with such a period of minimal activity suffices to enable the heart to build up a reserve so that symptoms will not readily reappear when normal or moderately limited activity is gradually resumed On the other hand, in very severe cases or in patients with a delayed therapeutic response, bed rest may have to be prolonged The advantages of prolonged bed rest (twelve to seventy two weeks) as compared with rest for a few weeks were reported by Davis[80] in a comparative study of patients with congestive heart failure Davis emphasized that bed rest should be continued for a variable number of weeks after the disappearance of evidences of failure in order that the heart may reach an optimum capacity for work

The whole question of duration of bed rest still requires study Fixed periods cannot be prescribed for all cases of heart failure since each presents an individual problem Certainly the very long periods mentioned above are not advisable for many patients with symptoms of moderate severity which respond rapidly to simple measures When patients have only mild symptoms, such as exertional dyspnea and when economic restrictions are placed on the rest period, a period of four to seven days in bed may suffice to begin treatment The response of symptoms to rest and resumption of activity will aid in determining whether longer periods of rest are necessary

The above mentioned periods of bed rest may be prolonged not only by a poor therapeutic response but by associated diseases which precipitated failure or by complications of heart failure Patients with acute coronary occlusion and failure may have to be kept in bed for four to six weeks and sometimes for several months The patients with active rheumatic fever should remain in bed as long as there are symptoms or signs of rheumatic activity It must be emphasized that complete bed rest is not terminated merely because the patient has already spent eight twelve or even twenty weeks in bed In the final analysis the clinical course of the patient and not an arbitrary time limit is the determining factor

The resumption of some degree of exertion as soon as this can be effected without danger, serves to improve muscular tone which aids the venous return to the heart and increases general physical fitness Rest should not be prescribed at all for patients whose dyspnea is associated with neurocirculatory asthenia or anxiety neurosis Neither is rest indicated merely because of the presence of cardiac disease if this disease is well compensated On the contrary controlled physical training a

desirable in these conditions in order to enable the patient to carry on normal activities

Complete Bed Rest

Sometimes rest in bed fails to bring about a satisfactory symptomatic improvement until it is rigidly enforced and activity is absolutely proscribed Bathroom privileges trips to the telephone getting out for meals and occasional excursions out of the bedroom may completely nullify the therapeutic effect of rest in bed When heart failure is associated with coronary thrombosis active rheumatic fever or other febrile diseases or when it fails to respond to partial limitation of activity, complete bed rest must be enforced

Complete bed rest does not imply that the patient must lie flat in bed Usually he is most comfortable if his head and shoulders are propped up by two or more pillows Special beds which permit elevation or depression of the upper or lower ends are ideal for obtaining the proper elevation of the head and chest When orthopnea is intense the position of the bed should be fixed so as to place the patient in a sitting position If the bed is not adjustable the patient may sit at the side of the bed with his feet hanging onto a chair and his back and head supported by pillows or the head of the bed may be elevated by blocks Adequate rest with maximum comfort is often best attained in a large cushioned chair Patients with severe congestive heart failure usually have a remarkable capacity for finding the position best suited for their circulatory status and the physician should help them attain and maintain that position with comfort and not arbitrarily modify it

The enforced use of the bedpan is often a distortion of the purpose of bed rest Straining at stool involves the Valsalva procedure and the concomitant risk of pulmonary embolism It is obvious that many patients will profit more from permission to use the commode at the bedside or even from one daily trip to the bathroom if necessary than they risk from these slight activities Elderly patients with prostatic enlargement likewise benefit more from commode or lavatory privileges than from extreme restriction to bed Similarly leg and breathing exercises and frequent changes of position in bed by minimizing the risk of phlebothrombosis and pneumonia are desirable activities which are not incompatible with the benefits of bed rest In summary the application of rest as a therapeutic measure requires judgment and individualization in each case the advantages and disadvantages must be carefully assayed

Mental Repose

Complete bed rest is ineffective unless there is mental as well as physical repose The sick room should be quiet and the atmosphere as pleasant as possible The shades should be drawn when the patient is napping Visiting hours should be completely restricted at first and limited later The patient should not be permitted to converse excessively Upsetting visitors or long discussions should be avoided Morphine is sometimes necessary the first few days in certain forms of heart failure but later milder sedatives will suffice (see below) However the indiscriminate administration of narcotics and sedatives is dangerous Sedatives and narcotics may interfere with the action of diuretics Sleep is essential if the rest treatment is to be effective soporifics should be administered when required Psychotherapy including optimism encouragement and reassurance will increase the advantages of rest The patient should not be permitted to become depressed by the thought that going to bed is the end stage of his cardiac disease or by the fear of chronic incapacity Often it can be honestly stated that complete rest in bed is not a desperate measure of last resort but one of limited duration utilized prophylactically to prevent more serious symptoms and to build up cardiac reserve so that the patient can resume his normal or restricted activity

Modified Bed Rest

If the symptoms of heart failure are mild e g if there is dyspnea only with moderate exertion it may not be necessary or economically feasible to put the patient to bed for a continuous period Similarly after a therapeutically successful period of complete bed rest modification of the restrictions may be permitted Bed rest may then be tempered with the privilege of leaving the bed for the bathroom or for meals If the indications are less urgent the patient may be required to go to bed one or two days a week usually at the week-end Or rest periods may be prescribed each day together with early retirement each evening An hour s rest (in bed if possible) after the noonday and evening meals an afternoon nap and resting for one to two hours before going out occasional evenings are all desirable forms of partial rest for patients

terpreted The physician must distinguish between essential bed rest and unnecessarily prolonged bed rest between the judicious use and the excessive abuse of rest A distinction should be drawn also between rest and recumbency For patients with congestive heart failure may obtain the desired rest, with more comfort propped up in a large chair or bed than when at complete rest in the horizontal position If bed rest is desirable, 8 to 10 inch blocks may be placed under the head posts to relieve orthopnea

The greatest danger of bed rest in patients with heart failure is the invitation to phlebo thrombosis and pulmonary embolism Deep breathing and leg exercises, changes in position and the use of anticoagulants are measures designed to overcome these dangers (p 572) The hazard of bronchopulmonary infection always lurking in patients with bronchial or pulmonary stasis due to congestive heart failure is enhanced by inactivity in bed especially in the obese, the indolent and the elderly The restricted judicious use of sedatives and narcotics will minimize the danger of complete immobility of the patient Exaggerated straining at stool in using a bed pan often enhances the danger of fatal pulmonary embolism

Elderly patients often become completely bedridden with prolonged bed rest Osteoporosis, bone atrophy and muscle wasting become intensified Urinary retention may be precipitated in patients with prostatism Constipation, cathartic habituation, back strain bed sores and psychoneurosis are among the other hazards attributed to complete and prolonged bed rest

Duration of the Rest Period in Bed

Rest may involve a complete stay in bed for a continuous period confinement during occasional days of the week or hours of the day or various modifications of these, or it may merely consist of a limitation of activity at work or at home These are discussed below

According to its severity heart failure may require the patient to remain in bed for periods of one to four weeks or longer Usually in uncomplicated cases of moderate severity, proper treatment combined with such a period of minimal activity suffices to enable the heart to build up a reserve so that symptoms will not readily reappear when normal or moderately limited activity is gradually resumed On the other hand, in very severe cases, or in patients with a delayed therapeutic response, bed rest may have to be prolonged The advantages of prolonged bed rest (twelve to seventy two weeks) as compared with rest for a few weeks were reported by Davis[80] in a comparative study of patients with congestive heart failure Davis emphasized that bed rest should be continued for a variable number of weeks after the disappearance of evidences of failure in order that the heart may reach an optimum capacity for work

The whole question of duration of bed rest still requires study Fixed periods cannot be prescribed for all cases of heart failure since each presents an individual problem Certainly the very long periods mentioned above are not advisable for many patients with symptoms of moderate severity which respond rapidly to simple measures When patients have only mild symptoms, such as exertional dyspnea and when economic restrictions are placed on the rest period a period of four to seven days in bed may suffice to begin treatment The response of symptoms to rest and resumption of activity will aid in determining whether longer periods of rest are necessary

The above mentioned periods of bed rest may be prolonged not only by a poor therapeutic response but by associated diseases which precipitated failure or by complications of heart failure Patients with acute coronary occlusion and failure may have to be kept in bed for four to six weeks and sometimes for several months The patients with active rheumatic fever should remain in bed as long as there are symptoms or signs of rheumatic activity It must be emphasized that complete bed rest is not terminated merely because the patient has already spent eight twelve or even twenty weeks in bed In the final analysis the clinical course of the patient and not an arbitrary time limit is the determining factor

The resumption of some degree of exertion as soon as this can be effected without danger serves to improve muscular tone which aids the venous return to the heart and increases general physical fitness Rest should not be prescribed at all for patients whose dyspnea is associated with neurocirculatory asthenia or anxiety neurosis Neither is rest indicated merely because of the presence of cardiac disease if this disease is well compensated On the contrary, controlled physical training is

It is the sodium and not the chloride ion which is responsible Ammonium chloride and potassium chloride exert a diuretic action whereas sodium bicarbonate is as water retaining as is sodium chloride

Sodium Restriction

Recent advances in understanding the relationship of odium and water to heart failure include a much greater emphasis on extreme restriction of sodium intake and less emphasis on the value of fluid restriction The physician must clearly and specifically indicate the exact quantity of sodium permitted in the daily diet, the ordering of a low sodium or low salt diet will evoke a remarkable variation in sodium intake usually excessive and ineffective Schroeder[271] showed that limitation of sodium chloride intake to 1 0 gm a day was usually enough to cause diuresis or prevent edema But in cases of severe heart failure of long duration it was necessary to reduce the intake of salt to as little as 0 5 gm (200 mg of odium) per day As a rule the treatment of congestive heart failure should begin with a sodium chloride intake of no more than 1 0 gm daily but the subsequent course may indicate that a more liberal allowance is permissible without recurrence of evidences of heart failure On the other hand the sodium intake may have to be restricted to 200 mg or less daily if the heart failure appears to be otherwise refractory to treatment Occasionally the requirements of hunger and palatability demand a more generous sodium intake than is ideally desirable but this may be compensated by the use of diuretics just as in diabetes a patient may prefer to take insulin rather than further to restrict his food allowance A more liberal sodium intake may also become permissible if the food to be ingested can be mixed with suitable cationic exchange resins which withdraw sodium and pass through the intestinal tract without being absorbed

A sharp limitation in salt intake may be effected by first placing the patient with heart failure on the Karell[190] regime which permits nothing by mouth except 800 cc of milk daily This allows about 1 gm of sodium chloride and 550 calories daily Even less sodium is obtained if salt poor powdered milk preparations are used such as Lonalac (Mead Johnson) or the more palatable Walker Gordon low sodium milk The advantage of the Karell regime is that it is a simple, fool proof method of assuring a low sodium diet until control over the patient can be effected and a more permanent regimen instituted

After a few days low sodium diets may be prescribed with more varied foodstuffs according to the patient's needs The normal daily diet contains 10 gm of sodium chloride or more The salt intake varies between 3 and 5 gm daily if no salt is added at the table and obviously salt rich foods are excluded Further reduction to 2 to 4 gm daily is effected by omitting all salt from cooking For stricter sodium poor diets detailed care is necessary in the choice of foods

The common sources of sodium are

1 Salt added in cooking or at the table Sodium bicarbonate Bisodol and other sodium-containing medicaments Baking soda Sodium containing tooth pastes Laxatives with sodium (e g sodium phosphates) Celery salt Garlic salt
2 Bread crackers pancakes salt-containing ready to-serve cereals cakes spaghetti, macaroni
3 Milk cheese salt butter margarine and sour cream
4 Smoked and salt cured meats and fish including ham bacon salt pork corned meats canned meats and fish shell fish sausages herring delicatessen meats clams crab heart kidney brains, lobster shrimp anchovies caviar
5 Bouillon and meat extracts used in soup Beer Pepsi cola
6 Canned vegetables soups Canned or frozen foods with sodium benzoate added
7 Spices and condiments including olives pickles catsup mustard sauces salad dressings relishes raisins dried figs
8 Pretzels popcorn salted nuts potato chips most candies and candy bars
9 Beets celery kale, lima beans sauer kraut spinach

Foods permitted in a low sodium diet include

1 Fresh fruits (raw or cooked) and fruit juices canned dried or frozen fruits or juices (unless label states that salt or sodium benzoate has been added)
2 Fresh or frozen green vegetables without salt Frozen peas are sometimes salted The following vegetables are usually permitted

Asparagus	Cucumber	Parsnips
Beans	Eggplant	Peas
Broccoli	Endive	Pumpkin
Brussels sprouts	Lentils	Radishes
Cabbage	Lettuce	Squash
Carrots	Mushrooms	Tomatoes
Cauliflower	Onions	Turnips
Corn	Parsley	Watercress

3 Potatoes rice cooked cereals prepared without salt Among the prepared cereals Puffed rice puffed wheat shredded wheat Barley Cream of Wheat, farina, hominy, macaroni, oatmeal

4 Passover bread (matzoth), special bread prepared with yeast but without salt and baking powder

5 Butter—only if unsalted olive oil and other vegetable oils shortening Spry, Crisco lard

6 Milk—limit to two glasses of dialyzed milk (Lonalac) Ordinary milk is relatively rich in sodium Unsalted cottage cheese

7 Meat fish or poultry prepared without salt, is moderately rich in sodium and should be limited to 3 or 4 ounces The following are usually permitted in low sodium diets chicken, turkey, lean beef (hamburger steak, roast beef, stew), lamb chops roast lamb, lamb stew, liver roast pork and pork chop, roast veal and veal chop, fresh fish (bass, cod, halibut oyster perch salmon, trout)

8 Egg—limit to one daily

9 Desserts and spreads Custards, junket, plain puddings using milk and egg from above allowance fruit pies with unsalted crust Jello jams jellies, marmalade, honey, sugar maple syrup, molasses ice cream prepared without salt unsalted nuts, sherbet, cakes cookies, muffins and fruit pies prepared with low sodium baking powder and without added salt

10 Beverages Tea coffee, carbonated drinks fruit juices ginger ale grape juice Coca cola lemonade Unsalted cream soups

Drinking water contains a minimal sodium content except in a few cities or in places where water softening equipment is used For very low sodium diets the sodium content of drinking water should be checked by inquiry from state or municipal laboratories The sodium content of the public water supply in certain cities has been analyzed and reported by Bills et al[29]

Palatability may be increased by seasoning with onions, pepper, lemon vinegar, curry, mint, mustard, caraway paprika sage garlic pimento, or by flavoring with cocoa chocolate, coffee caramel, maple peppermint, lemon, orange vanilla, cherries, cloves cinnamon, nutmeg ginger, salt poor mayonnaise, salt poor French dressing

Potassium chloride is sometimes substituted for sodium chloride as in Neocurtasal (Winthrop) This is acceptable to some patients but is somewhat bitter and unsatisfactory for most While Neocurtasal contains substantial amounts of ammonium chloride as well as small amounts of potassium and calcium formate and magnesium citrate, Diasal is essentially potassium chloride with a trace of glutamic acid[274] It appears to be the most generally preferred sodium chloride substitute both for addition to prepared food and for use in cooking Co salt resembles Neocurtasal in its potassium and ammonium chloride contents but also contains small amounts of calcium phosphate and choline Gustamate contains monoammonium glutamate glycine and glutamic acid Patients often complain of its after taste In the presence of associated renal insufficiency potassium salts should not be administered because of the risk of inducing toxic effects or death from hyperkalemia Lithium salts, used as sodium substitutes to improve palatability have been reported to cause serious toxic manifestations and fatalities [illegible][16]

When the sodium intake must be stringently reduced to no more than 200 mg sodium daily it is necessary that the physician be familiar with the sodium content of all of the more common foods which may be taken by the patient The regular white and rye breads contain about 170 mg sodium per slice (ounce) It is apparently extremely difficult or virtually impossible to formulate a reasonable 200 mg sodium diet (500 mg sodium chloride) and permit the use of regular bread An 8 ounce glass of milk contains 125 mg sodium and an ounce of cream 10 to 15 mg There are 40 mg of sodium in an egg and 15 to 25 mg sodium per ounce of most forms of poultry, fish or meat White meat of poultry has less sodium than dark meat

In planning a low sodium diet[330] the following list and quantities may be used to formulate a basic 200 mg diet The proper caloric allowance is then obtained by adding the

desired amount of salt free bread or cakes potatoes rice spaghetti noodles and fats Increases in sodium allowance can be obtained by substituting variable quantities of regular milk for low sodium milk (Lonalac) regular bread for salt free bread or additional meat or egg Even more rigid sodium restriction is represented by the Kempner diet (p 935) which consists entirely of rice fruit fruit juices sugar and vitamin supplement *and contains 100 to 150 mg (4 1 to 6 5 mEq)* of sodium Sometimes the effectiveness of rigid sodium restriction in heart failure is not demonstrated until the patient is placed on the Kempner diet partly because he is less apt to err in his dietary intake when the latter is so rigorously simplified

At best, very low sodium diets are unpalatable monotonous and difficult for most patients to follow for extended periods of time For this reason every effort must be exerted to make the food as attractive as possible by careful attention to variety in the choice of foods to the liberal use of permitted spices and herbs to the use of salt substitutes to home-made preparation or purchase of bread cakes candies of low sodium content *and to attractiveness in serving the* food A number of leaflets manuals and cookbooks have been published which aid in the planning and preparing of low sodium meals [144 372 377 380]

The value of restricting sodium seems apparent in patients with anasarca and serous

Table 7 Basic 200 mg Sodium Diet

FOOD	QUANTITY PER DAY	SODIUM CONTENT mg
Meat poultry or unsalted fish	5 oz cooked	100 125
Egg	1	40
Vegetable (see those permitted above)	3 avg portions (300 gm)	25
Fruit	4 average portions	8
Lonalac milk	1 pint	10
Fats	20 gm	1
Salt-free bread or salt free matzos or cereal	according to caloric need	
Rice noodles potato	1 serving	
Salad with saltless dressing		
Beverage	3 servings	
Sugar		
Jelly		

To increase the above to 500 mg sodium daily one may increase the meat or egg allowance or add regular milk (125 mg per 8 oz glass) or one may permit one or more slices of regular bread (170 mg sodium per slice) or combinations of these Thus 1 glass of regular milk and 1 slice of regular bread would increase the above 200 mg diet to a 500 mg diet

To increase to a 1 gm sodium (2 5 gm sodium chloride) daily intake one pint of milk (250 mg sodium) 3 slices of regular bread (500 mg sodium) 6 oz of meat poultry or fresh fish (120 mg sodium) 2 eggs (80 mg) may be taken in addition to permitted fruit vegetables cereals fats etc provided that no salt is used in cooking or at the table The quantities of fats starchy vegetables salt free or regular bread permitted will be determined by the desired total caloric intake but with due regard for the sodium allowed

effusions Such restriction is believed to interfere with the transudation of fluid from the blood stream into the tissues it may actually cause a reversal of flow and diuresis It is equally important to recognize the benefits of salt restriction in patients with left sided heart failure who have no obvious edema Attacks of nocturnal dyspnea and cough or of pulmonary edema may be prevented by sodium restriction In some nonedematous patients with congestive heart failure the presence of extensive occult edema is sometimes indicated by a sharp diuresis and the loss of 5 to 10 pounds in weight when fluids and salt are restricted usually in combination with other therapeutic measures

Patients vary greatly in their tolerance of salt restriction Many become habituated to rigid limitation of salt and suffer no discomfort whether or not substitutes are used Others react badly with even mild depriva

tion Occasionally the limitation of sodium together with its excessive elimination due to powerful diuretics leads to severe electrolyte disturbances in the blood and serious clinical manifestations (p 275) It may be necessary to increase the sodium allowance in such cases In some patients extreme sodium restriction and vigorous mercurial diuresis diminish glomerular filtration and further enhance the renal impairment of sodium water excretion However, the risks involved are relatively rare and minimal compared to the advantages that have accrued from the use of the mercurial diuretics and very low sodium diets These dangers should not be exaggerated lest many patients with heart failure be deprived of the two therapeutic measures which represent our greatest advance in the past twenty five years in the treatment of this condition

Fluid Intake

It has long been the practice to restrict the intake of water by patients suffering from congestive heart failure especially in the presence of edema Yet recent evidence indicates there is usually no primary impairment in the excretion of water However the cardiac patient who is unable to excrete sodium properly and has a positive balance with respect to this ion will also retain fluid in sufficient quantity to keep his extracellular fluid isotonic In fact when sodium intake is restricted to minimal levels the ingestion of plain water even in large amounts may actually augment diuresis and diminish edema in some cases

Recent studies by Schroeder[287] Schemm,[291] Bridges et al [] Leevy et al [207] and Gorham and his associates[151] have demonstrated the effectiveness of *very low* sodium intake in cardiac failure if at the same time water intake was not restricted When the diet contained less than 1 gm of sodium chloride daily Schroeder observed an occasional increase in diuresis when the patient took generous quantities of fluid and a diminution when fluids were rigidly restricted Schemm employed a diet containing less than 2 0 gm daily and claimed beneficial results from forcing fluids to 5000 cc and over daily

Gorham et al [151] observed that with low sodium diets the net loss of sodium and edema was greater when patients were *encouraged* to take 3000 cc of fluid daily than when they were restricted to 1500 cc, but little added benefit accompanied the forcing of fluids above 3000 cc Gorham et al suggested that the fundamental object was the maintenance of a low sodium intake relative to the water intake rather than a low sodium or high water intake per se, because of the dehydrating effect of hypotonic salt solution Studies by Crutchfield and Wood[73] of urine volume and total renal sodium excretion during water diuresis disclosed that water diuresis per se increased sodium excretion if the urinary output was previously low But water diuresis diminished the sodium excretion if the previous urinary volume exceeded 2 to 3 liters daily These studies suggest that maximal sodium excretion and urinary output can be obtained in most patients with heart failure on a given sodium allowance when the water intake is between 2 and 3 liters daily

Studies with water loads indicate that as a rule cardiac patients respond with a diuresis after about 50 to 60 minutes as normal individuals do But the quantitative response is often below normal The reduction in diuretic response may be striking in patients with congestive heart failure In some patients with very severe heart failure and marked edema the administration of a water load may result in water retention Abnormal retention of ingested water is particularly common in patients with so called refractory heart failure Whether this water retention is entirely secondary to extreme sodium retention or whether there is an independent antidiuresis of water in severe heart failure is uncertain Because of this abnormality in excretion of water I have come to restrict the intake of *fluids as well as sodium* in those patients who appear to suffer from intractable heart failure and whose plasma sodium is greatly diminished (p 275)

Diet

Except for the restriction of salt, the diet is not usually a major element in the treatment of congestive heart failure The two main principles to be followed when there is no contrary indication are (1) low caloric intake and (2) small, *frequent feedings* Otherwise the general rules of dietetics are followed Often the diet is determined by associated conditions such as fever, obesity or malnutrition avitaminosis anemia diabetes

The benefits of a low caloric diet result from its reduction of the work of the heart This is due to the fact, demonstrated by Proger and

Magendantz[267] that dietary restriction causes a sharp decrease in the basal metabolic rate and a significant lowering of the cardiac output the blood pressure and the heart rate At the same time the patient s vital capacity is increased and he is able to perform more work Low caloric diets are especially indicated in obese patients with hypertensive and coronary heart disease—particularly when they are confined to bed by symptoms of heart failure On the other hand children with cardiac failure and active rheumatic carditis are usually undernourished as are often patients with cardiac failure secondary to avitaminosis and those with advanced right sided heart failure Dietary restriction may be unwarranted or deleterious in such cases In some cases of heart failure especially those due to constrictive pericarditis hypoproteinemia may be severe A high protein intake appears desirable in such cases Patients with diabetes and coronary heart disease who require insulin therapy should receive an adequate carbohydrate allowance in order to avoid anginal pain due to hypoglycemia (insulin shock)

The total food intake should be divided so as to give small *frequent feedings* (five to six times daily) This avoids excessive gastric filling with consequent abdominal distention elevation of the diaphragm and diminution in vital capacity Patients who suffer from nocturnal dyspnea cough or pulmonary edema should take neither food nor fluids after an early evening meal

The *vitamin content* of the diet should be adequate or supplemented by vitamin concentrates In particular vitamin B should be added to the diet by giving thiamine chloride 5 to 10 mg daily in divided doses and brewers yeast 4 tablets three times daily When there is reason to suspect a vitamin B_1 deficiency as a prime or contributing cause of the failure 20 to 100 mg of thiamine chloride should be given daily parenterally followed after a brief interval by 10 to 20 mg daily by mouth Recently there has been interest in the occurrence of thiamine deficiency as a result rather than a cause of congestive heart failure Anorexia due to venous congestion of the gastrointestinal tract or cardiac drugs hepatic dysfunction and the prolonged use of diuretics are factors in heart failure which may lead to thiamine deficiency[257] This is especially important since cocarboxylase derived from thiamine is required for utilization of pyruvate by the heart muscle Protein and niacin deficiencies often accompany a deficiency of thiamine chloride and these should likewise be corrected

Palatability of the diet is extremely important This should be attained by care in the preparation and serving of the food and a choice as far as feasible from among those foods which the patient prefers and knows he can tolerate Usually a *bland, low residue* diet is better tolerated than one with considerable roughage since the latter tends to cause distention and flatulence Cheeses cabbage Brussels sprouts and other members of the cabbage family chocolates nuts pastries gravies fried foods and charged waters should be avoided because of their tendency to cause distention and flatulence Most patient do not tolerate raw fruits or large quantities of fruit juices which may cause not only distention but also heartburn and other symptoms of gastric hyperacidity or pylorospasm Milk should be excluded if it is not well tolerated

Alcohol There is no specific objection to the ingestion of moderate quantities of alcohol except in so far as it adds to the caloric intake *Small amounts* of sherry whiskey or brandy are often of benefit especially to the aged to those suffering anorexia and weakness and to patients with coronary artery disease and angina pectoris But alcohol is detrimental to patients with associated peptic ulcer or gastric hyperacidity with irritable colon or colitis or with prostatism

Tobacco There is no clear evidence of harm from smoking so far as heart failure itself is concerned but as a rule dyspnea and especially cough due to left sided heart failure are intensified by smoking If it is too difficult to discontinue the habit moderate smoking (5 cigarettes or less or 2 cigars daily) is permissible provided no unfavorable symptoms are produced However if palpitation or extrasystoles occur if there are heartburn and other evidences of gastric distress cardiac or epigastric pain or if the patient suffers from coronary heart disease with angina pectoris I believe it preferable to discontinue smoking entirely In my experience patients find it easier to stop completely than gradually to reduce the number of cigars or cigarettes smoked daily I make a determined effort to persuade all cardiac patients to discontinue smoking

Coffee and Tea There is usually no objection to two or three cups of coffee daily In fact this may be desirable for patients with coronary heart disease But if this amount of coffee causes nervous irritability, sleeplessness, palpitation or indigestion, it should be avoided Sanka or weak tea may be substituted If strong tea is taken, the same limitations apply as for coffee

Bowels A satisfactory daily bowel movement is desirable Straining at stool must be avoided especially if the patient suffers from coronary heart disease There is danger of precipitating an acute coronary occlusion in such patients or of rupturing the heart wall if it is the site of a recent infarction The risk of pulmonary embolism due to straining has been mentioned Mineral oil (1 to 2 tablespoons) should be administered each night if the stool is hard A satisfactory bowel habit may be established if the patient tries to defecate each day at the same time and avoids other times For the first few days after a coronary occlusion or after the administration of opiates it is preferable to have no bowel movement at all unless this occurs easily and without catharsis Patients in bed usually require some assistance Mild laxatives such as milk of magnesia (1 to 2 oz), cascara sagrada (5 to 10 grains) or compound licorice powder (2 teaspoons) should be given nightly until a soft movement results Enemas should be given if necessary unless they weaken the patient unduly I have found a well given colon irrigation preferable to an enema and better tolerated by the patient

Cationic Exchange Resins[9, 231, 154, 348, [illegible], 59]

Adherence to very low sodium diets containing 500 mg or less daily is virtually impossible for some patients and very difficult for most especially if such dietary restriction must be continued for more than a few weeks After Dock[9] introduced the use of cationic exchange resins for the removal of sodium from the gastrointestinal contents, these resins gave promise of great therapeutic value in solving the problem of low sodium diets This promise has not yet been realized

Ion exchange resins are insoluble inert non absorbable ion-containing synthetic polymers of high molecular weight whose structure provides large surface areas permitting the selective exchange of its ions for other ions of similar charge Cationic resins are weakly acidic polyacrylic resins, usually containing either carboxylic or sulfonic groups, which remove from solution positive (basic) ions such as sodium, potassium and calcium in exchange for their own hydrogen, ammonium or other cations Sulfonic resins are effective at pH 3 to 10 and therefore actively exchange their ammonium or potassium ions for hydrogen ions in the stomach Subsequently the hydrogen ions are exchanged in the intestine for sodium potassium and calcium Ammonium ions released by the resins are absorbed and converted into urea by the liver Carboxylic resins are effective at pH 8 to 11 and are active in the alkaline intestine where their cations are exchanged for basic ions especially sodium

In vitro the cation resins show binding preference for ions with higher molecular weight and greater valence and therefore for calcium magnesium, potassium and sodium in this order But since the concentration of ions in solution is a determining factor, in the intestine the cationic resins bind predominantly sodium, which is highest in concentration and to a lesser extent potassium and calcium in that order In vivo, the binding power of the resins depends also on the sodium intake,[7, [illegible], 154, 381] 1 gm of resin binding about 1 to 1 5 mEq when the daily sodium intake is 2 gm or more, whereas 1 gm of resin may bind only 0 5 to 1 0 mEq of sodium when the daily sodium intake is only 200 mg to 1 gm The sodium binding of the cation resin is also dependent on the amount of sodium available for transport across the intestinal wall into the gut The sodium and other cations removed from the solution of intestinal contents may have originated exogenously in the diet or endogenously in the intestinal pancreatic or biliary secretions[106, 39, 348, 96]

The resins and the basic ions bound by them are not absorbed, but are excreted in the feces Clinical and experimental studies have shown that following the administration of cationic exhange resins the fecal excretion of sodium and potassium is increased and their urinary excretion diminished whereas the urinary excretion of chloride is enhanced[184, 27, [illegible], 104] A negative sodium balance may be achieved by marked increase in fecal sodium[39] If the administered cationic resin is of the hydrogen or ammonium series i e saturated with hydrogen or ammonium ions it releases these ions in the intestinal tract where

they combine with chloride the ultimate effect being similar to that of administered hydrochloric acid or ammonium chloride The action of the resin in depleting sodium in the intestinal contents is supplemented by the possible diuretic effect of an acidic chloride This may account in part for the observation that resins like ammonium chloride, may potentiate the diuretic effect of a mercurial [104, 39] The absorption of free chloride ions may not only increase the concentration of plasma chlorides but also reduces that of bicarbonate and induces acidosis[136, 154] the latter is usually mild and not responsible for clinical manifestations in the doses of resins usually prescribed The removal of potassium ions by resins may result in depletion of body potassium and hypokalemia[78, 154, 312] if this loss is not balanced by adequate dietary intake of potassium or potassium supplement Theoretically calcium may also be depleted, but balance studies show little increase in fecal calcium during resin administration and calcium depletion has not been a clinical problem

Preparations Dosage and Administration Three of the commercially available cationic resins are of the carboxylic type—Carbo Resin Resodec and Natrinil *Carbo Resin* contains 87 5 per cent cationic resin and 12 5 per cent anionic resin, the latter having been added to bind hydrogen ions in the stomach and thus neutralize the tendency of cationic resins to induce acidosis [97] The claim that addition of the anionic resin increases exchanging efficiency has been questioned The cationic resin itself in this preparation is two thirds saturated with hydrogen ions and one third with potassium The latter is designed to prevent potassium depletion and obviate the need for potassium supplements The recommended daily dose is 16 gm three times daily at mealtime This resin is available in bulk powder (1 pound bottles) or in 8 gm packets *Resodec* is saturated with ammonium and potassium ions in the ratio of 2 1 The recommended dose is 15 gm of powder (1 packet) three times daily at meals *Natrinil* is saturated four fifths with hydrogen and one fifth with potassium The recommended dose is 1 tablespoon or 1 packet (10 gm) four times daily i e at meals and on retiring A fourth cationic resin *Katonium* is a sulfonic type cation resin and is three quarters saturated with ammonium one quarter with potassium ions The dose is 15 gm three times daily at meals

The resins may be taken with water milk tomato juice, orange juice or other beverage including the colas or beer preferably chilled They may also be mixed with various foods such as cereals applesauce mashed potatoes Jello, ice cream Cookies and other preparations may be made with the resins according to recipes supplied by the manufacturers They have been administered continuously for prolonged periods without noticeable toxic effects [336, 343, 93, 345] but they may also be prescribed intermittently for periods of four or more days with intervals without resins [163]

Indications Clinical Value and Side Actions [77, 199, 81, 136, 154, 346] Resins are designed chiefly to reduce the amount of sodium absorbed when the dietary sodium restriction is inadequate to obtain the desired therapeutic effect Theoretically the same objective can be attained by minimizing the sodium intake to 200 mg or less as by use of the rice diet of Kempner In practice patients often cannot or will not follow such a regimen for the necessary prolonged period If the patient may be allowed a daily sodium intake of 1 2 gm (3 gm of sodium chloride) the diet can be made fairly tolerable the administration of resins at the same time serves to reduce actual sodium absorbed to the equivalent of that of a 200 to 400 mg sodium intake If 1 gm of the resin binds 1 mEq of sodium in the intestinal tract then 45 gm daily binds 45 mEq or about 1000 mg of sodium Thus only 200 mg of the 1200 mg of sodium ingested is absorbed

It is apparent however that the resins do not permit an unrestricted sodium intake when low sodium diets are necessary Nor do resins substitute for any other therapeutic measures indicated for the treatment of heart failure Mercurial diuretics may be required less frequently or not at all after the institution of resin therapy but this effect might be attained also if sodium intake were properly restricted It is questionable whether cationic resins should be used for the treatment of heart failure in patients who can be controlled on diets containing 1 2 gm of sodium or more daily

Essentially cation exchange resins are indicated in the treatment of heart failure when sodium intake must be limited to 200 mg daily and the patient refuses to follow this

regime or there is doubt as to his adherence to it It has been my experience many times that hospital patients supposedly on a 200 mg diet, excrete more sodium in their urine than appears possible if the diet were followed properly Following the administration of resins the urinary sodium falls to 7 mEq (200 mg) or less, and a more satisfactory clinical response is obtained than was previously possible There have been many reports of clinical improvement after institution of resin therapy when the response to all other conventional therapeutic agents had previously been unsatisfactory[198 105 863 199 27 96 259 25] The urine volume increased, the patient's weight fell and edema diminished or disappeared The need for mercurial diuretics was frequently minimized or abolished after institution of cation exchange resin Dyspnea and orthopnea have been relieved[118] Cationic exchange resins are indicated in all cases of intractable failure when there is no apparent cause for refractorness to treatment Several times I have noted a gratifying clinical improvement in patients with refractory heart failure after cationic resins were added to the therapeutic regimen Mercurials previously ineffective induced satisfactory diuresis and helped to restore compensation This is by no means the usual or even common effect of resins in refractory heart failure

The chief risk of cationic exchange resins is the development of metabolic acidosis with hyperchloremia, but this is rarely a significant danger except in the presence of renal insufficiency[348] The latter is generally regarded as a contraindication to cation resin therapy A second side action is the depletion of potassium in patients in whom the potassium bound by resin is not replaced by an adequate food intake because of anorexia or nausea Digitalis intoxication has been precipitated by potassium depletion due to resins[118] Resins intensify the potassium depletion that may result from concomitant diarrhea or the continued use of mercurial diuretics and ammonium chloride Potassium ions now included in the cation resins tend to reduce this risk Salt substitutes such as Diasal and Neocurtasal also help to supply potassium Potassium supplements may also be given In patients with hepatic dysfunction there may be some danger of ammonia intoxication if the ammonium type of resin is used Occasionally hypocalcemia may follow prolonged resin therapy,[154] but this may be prevented by giving 0 3 to 0 5 gm of calcium lactate or calcium gluconate orally three times daily Although the occasional complications of resin therapy should not be forgotten it is perhaps equally or more important to stress that cation resins have been administered for long periods of time without harm[335] Furthermore, such resin therapy has been safely administered to outpatients without complication even in the absence of strict chemical control[304]

From the practical point of view the chief objections to cationic resins include their usually unpleasant taste their bulk and their constipating effect Occasionally there are unpleasant digestive disturbances including anorexia nausea vomiting, epigastric burning abdominal cramps and diarrhea abdominal distention or fecal impaction Furthermore at the present time resins are relatively expensive for long term therapy Finally, patients generally refuse to continue the use of resins For all these reasons cation resin therapy after a brief flurry of endorsement has not taken hold in the management of heart failure Considering that the objective of resin therapy is to overcome the difficulty of maintaining extreme sodium restriction because of the impalatability of low sodium diets, the available resins have failed in that they are at least as impalatable or as difficult to take for many patients as the low sodium diets Nevertheless the therapeutic possibilities of the resins are such that it is to be hoped that they will continue to be improved with respect to the efficiency of their exchange capacity their consistency and palatability and not the least their high cost At the present time they may be useful as an adjunct when other measures for the treatment have failed or when the resins are tolerated better than the extremely low sodium diets

DIGITALIS AND RELATED DRUGS

Next to rest digitalis has been the most valuable agent in the treatment of congestive heart failure since Withering[255] in 1785 called attention to the beneficial effect of foxglove on dropsy In many cases of heart failure the combination of a brief period of bed rest and digitalization suffices to ameliorate or eliminate symptoms Many patients with limited cardiac reserve are enabled to conduct a

somewhat restricted but relatively normal life over a period of many years by the judicious restraint of physical exertion and the maintenance of digitalis therapy

THE ACTION OF DIGITALIS

The pharmacology of digitalis has been studied extensively (for details see the monographs of Cushny [74] Weese [328] Luten [201] and Moritt[247, 214]) but several of the actions of this drug are still obscure From the viewpoint of clinical application the following are most important

Improvement of Myocardial Function

The most important cardiac action of digitalis is a direct beneficial effect on myocardial contraction The digitalis glycosides enter the myocardial cells[140] where they yield active aglycones which in some unknown manner produce a more forceful systolic contraction of the heart There is experimental evidence suggesting that digitalis may favor the polymerization of actin and the shortening of actomyosin fibrils [278] Perhaps the latter is related to the effect of digitalis on myocardial potassium [62] membrane permeability to electrolytes and transmembrane potentials [3 3] which are concerned with the shortening of actomyosin (p 132) The studies of Clarke and Mosher[6] indicate that digitalis restores to normal values the diminished potassium and increased sodium concentration found in the heart muscle in congestive failure On the other hand infusions in dogs of acetyl strophanthin increased the potassium concentration in coronary sinus blood compared with arterial potassium concentration whereas the coronary sinus sodium concentration and the pH were lower This suggested that the drug caused potassium and hydrogen to leave and sodium to enter myocardial cells [174] Other studies with the aid of radioactive potassium (K^{42}) showed that digitalis reduced the exchangeable and tissue potassium content [15]

Studies of the effect of digitalis on myocardial metabolism indicate that the drug increases cardiac work in low output heart failure without a significant increase in coronary flow oxygen consumption or substrate extraction [21 3] Olson et al [257] observed that acetyl strophanthidin reduced glucose uptake without affecting the extraction of oxygen pyruvate or lactate Variable effects on contraction of the normal and failing heart were related to physical chemical properties of cardiac myosin

The over all effect of digitalis appears to be a more efficient utilization of phosphate bond energy by the actomyosin fibril [257 3] That digitalis promotes myocardial contraction has been repeatedly demonstrated experimentally in strips of heart muscle the isolated heart and the heart lung preparation [74 65] Schaefer [296] using the heart lung preparation demonstrated more forceful ventricular contraction and more complete emptying, the digitalized heart could expel its contents against a significantly higher arterial resistance than could the undigitalized heart More recently Cattell and Gold,[56] using the isolated papillary muscle of the cat and Kabat and Visscher [188] using the tortoise heart, similarly demonstrated striking increases in the force of systolic contraction and the work capacity of the heart muscle respectively following the administration of digitoxin ouabain or K strophanthoside Studies of the action potentials of single cardiac muscle fibers of the frog disclosed that digitalis and other cardiac glycosides shortened repolarization without affecting depolarization [365]

Digitalis not only increases the force of systolic contraction the capacity of the heart for work and the completeness of ventricular emptying but also enhances the efficiency of myocardial contraction For Gremels [150] using the heart lung preparation noted that following the administration of strophanthin the heart utilized less oxygen for a given amount of work Similar observations of Moe and Visscher[243] also indicated that digitalis bodies increase cardiac efficiency so that a greater percentage of energy expended is converted into external work Bing and associates[31 30] likewise reported that digitalization of patients with congestive heart failure resulted in an increase of the cardiac output without an alteration in coronary blood flow or oxygen consumption, hence there was an increase in mechanical efficiency In other words, digitalis increased the amount of mechanical work developed at a given oxygen expenditure—a reversal of the basic energy disturbance in myocardial failure [62 112] The effect of cardiac glycosides is apparently not on the production of energy but on the utilization of energy provided by the high-energy phosphate bonds [360] Studies in which human cardiac muscle was exposed

in vitro to radioactive (C^{14}) digitoxin suggested that digitoxin acts catalytically without itself being converted to carbon dioxide[50]

Because of these observations and others to be discussed below it appears probable that the major benefit of digitalis in heart failure is due primarily to its improvement in cardiac contraction and efficiency and only secondarily in certain cases to slowing of the heart rate Thus in cases with regular sinus rhythm, digitalis may lead to clinical improvement of heart failure without concomitant slowing of the heart rate or before such slowing occurs Furthermore although there is no direct conclusive evidence in humans such a myocardial action of digitalis has better experimental support and is more consonant with known observations than the suggested hypothesis of an extracardiac (peripheral vascular) action We have seen that the signs and symptoms of congestive heart failure and their localization are ultimately determined by the inability of a failing chamber to handle the venous return especially when this is increased during activity By augmenting the force of cardiac contraction and improving myocardial efficiency digitalis enables the venous return to be accepted and ejected, reduces the elevated venous pressure increases the cardiac output and restores compensation

Slowing of the Cardiac Rate

The rate of the heart is commonly accelerated in congestive heart failure, but this acceleration is especially pronounced and significant in those cases in which failure is associated with atrial fibrillation In the latter group especially digitalization rapidly effects a reduction in the ventricular rate to normal levels, concomitantly there is usually a striking amelioration in the clinical manifestations of heart failure Slowing of the heart by digitalis glycosides may be mediated by (a) vagal stimulation or (b) direct myocardial action on the atrioventricular node and bundle whereby their refractory period is prolonged[38] and atrioventricular conduction is depressed

Vagal Stimulation That digitalis produces slowing of the heart through vagal stimulation is indicated by observations both in animals and man, that such slowing is diminished or abolished by vagotomy or the administration of atropine[74] The vagal component is dominant with early therapeutic doses for Gold and his associates[149] showed that atropine increased the ventricular rate in atrial fibrillation after it had been slowed by digitalis But after full digitalization the rate could no longer be accelerated by atropine presumably because with larger doses slowing was mediated by extravagal means

The exact method by which digitalis induces vagal slowing of the heart is uncertain Heymans and his co-workers,[178] in cross circulation experiments, slowed the heart rate of dogs by perfusing the carotid sinus with digitalis Similar perfusion of the vagus center produced no slowing if the center was isolated from the afferent sinus nerves These experiments suggested that digitalis slowing was effected by action of the drug on the perceptors of the carotid sinus with a consequent reflex increase in vagal tone, and a diminution of the rate of impulse formation in the sinoatrial node

However, there is more evidence that this reflex vagal effect at least in congestive heart failure is not due to direct action of digitalis on the sinus receptors, but to afferent stimuli initiated when the failing heart muscle is restored to compensation by direct myocardial effects of digitalis In persons with normal hearts digitalis causes slight or no slowing except with toxic doses Digitalis reduces the cardiac rate in tachycardias only when the tachycardia is due to heart failure In patients with atrial fibrillation digitalis induces more striking slowing of the heart when there is associated heart failure than in cases of atrial fibrillation without heart failure All these observations seem to support the concept that digitalis in therapeutic doses exerts its slowing effect essentially in the presence of failure and that the reduction in cardiac rate is secondary (by way of vagal reflexes) to the digitalis induced improvement in myocardial function[2 1]

That tachycardia is a compensatory reaction to cardiac failure has been discussed Presumably the tachycardia is initiated by an elevation of venous pressure with a consequent Bainbridge reflex Elimination of this tachycardia requires abolition of the myocardial failure which induced the increase in heart rate By causing a more forceful cardiac contraction and more complete emptying digitalis relieves the heart failure, reduces the venous pressure and abolishes the reflex responsible for the compensatory tachycardia

Depression of Atrioventricular Conduction

Digitalis impairs the conduction of impulses from the atrium to the ventricle partly by vagal stimulation but also and predominantly through the direct action on the junctional conduction tissues. This occurs both in healthy and decompensated hearts and is disclosed electrocardiographically by prolongation of the P-R interval and with more toxic doses by more severe degrees of atrioventricular heart block. Lewis and his co-workers[214] demonstrated a digitalis-induced inhibition of atrioventricular conduction even when vagal depression was excluded by atropine in dogs in which the atria were stimulated to produce a rapid atrial rate as in fibrillation. According to Mendez and Mendez[33] the diminution in atrioventricular conduction to the point of atrioventricular block is due to an increase in the refractory period of the atrioventricular propagating tissue.

According to Mackenzie[23] and to Lewis[38] depression of atrioventricular conduction by digitalis accounts for its usefulness in cases of atrial fibrillation with rapid ventricular rate in which the drug's most striking benefits are clearly demonstrable. When the atria fibrillate they may discharge 400 or more impulses per minute to which the harried ventricles may respond with 100 to 160 contractions per minute. But these ventricular contractions are less efficient than normal because (a) the diastolic recovery period is diminished by the tachycardia and (b) the atrial impulses arrive so rapidly and irregularly that many ventricular contractions occur too soon after the previous one to permit adequate filling or expulsion of blood. Therefore many of the ventricular contractions are too weak to open the aortic valve or produce a palpable radial pulse (pulse deficit).

According to the Mackenzie[5] concept digitalis by impairing atrioventricular conduction diminishes the frequency of impulses bombarding the ventricles and thereby slows the ventricular rate. Consequently more effective systolic contraction and emptying are possible, the pulse deficit is eliminated and compensation restored. According to Luten and Jefreys the digitalis effect on atrioventricular conduction is of secondary importance in accounting for myocardial improvement in cases of atrial fibrillation and heart failure. As stated above clinical improvement is attributed to direct action of digitalis on the myocardium with stronger cardiac contraction. The ventricular slowing is then due (a) partly to vagal reflexes as myocardial function improves and (b) to increase in the refractory period of the ventricular myocardium due to its stronger contraction thereby rendering the heart muscle unresponsive to most of the atrial impulses. According to this explanation increased myocardial refractoriness due to more forceful contraction is more important than impaired atrioventricular conduction in explaining the digitalis effect in cases of atrial fibrillation with heart failure. On the other hand recent studies by Mendez and Mendez[35] indicate that while digitalis increases the refractory period of the atrioventricular conduction system, it shortens the refractory period of ventricular muscle and that the latter accounts for the occurrence of ventricular premature beats and the susceptibility to digitalis ventricular fibrillation. However these effects may appear only with relatively large doses.

Peripheral Action of Digitalis

The possibility that the beneficial effect of digitalis in congestive heart failure is due essentially to a peripheral action[10] whereby the venous return is diminished by venoconstriction is discussed below under the heading Cardiac Output and Venous Return.

Digitalis and Cardiac Size

There is uniform agreement that in the heart-lung preparation in normal animals, in normal persons and in patients with congestive heart failure digitalis reduces the size of the heart.[65, 316, 44] Cardiac failure is associated with an enlarged heart which as shown by Starling and Visscher[314] is inefficient because it consumes relatively more oxygen than the normal heart for the performance of the same amount of useful work. By diminishing the size of the dilated decompensated heart digitalis increases its fitness or functional capacity so that it carries out its work with a lesser volume, a lesser oxygen consumption and therefore with greater efficiency.

On the other hand one must not mistake cause and effect. The development of cardiac enlargement in congestive heart failure is a consequence of an increasing residual of blood with increased lengthening and hypertrophy of the myocardial fibers. This may serve as a compensatory mechanism by which the fa

tigued and damaged heart attempts to maintain an adequate output. Conversely, reduction in size of the enlarged heart by digitalis may not be a direct effect of digitalis but rather a reversal of the process of dilatation as the digitalis promotes the strength and efficiency of myocardial contraction. Consequently there is less residual of blood, less stretch of myocardial fibers and less "compensatory" enlargement than before digitalization. The experiments of Cattell and Gold[58] indicate that digitalis acts directly on the heart muscle to increase the tension which it can develop during systolic contraction without a primary change in the diastolic length of the muscle. In addition to the direct benefit of digitalis for the heart muscle, the secondary reduction in heart size is itself advantageous because of the lesser oxygen requirement and the greater efficiency of cardiac contraction.

Digitalis and Circulatory Dynamics

The clinical benefit of digitalis in heart failure has been shown to be based primarily on its direct improvement of myocardial contraction and efficiency and in part or secondarily on slowing of the cardiac rate. In addition digitalis tends to restore to normal the various aberrations in circulatory dynamics which develop in the course of heart failure. These effects, like the reduction in cardiac size, are probably not direct consequences of digitalis activity but secondary to strengthening of cardiac contraction and enhanced cardiac emptying.

Cardiac Output and Venous Return. In the heart lung preparation digitalis may produce a temporary increase in cardiac output after the heart dilates. But in normal dogs, in dogs with compensated valvular lesions and in normal men, digitalis reduces the cardiac output.[65, 92, 316]

In cases of heart failure Stewart and his associates[316] and others[1, 9, 101] observed an almost constant increase in cardiac output following digitalization. McMichael and Sharpey Schafer,[235] using the method of intracardiac catheterization, observed striking and *uniform* augmentation of cardiac output following the administration of digitalis to patients with congestive heart failure. Bloomfield et al.,[33] using the same technique, observed a uniform increase in cardiac output (due to increase in stroke volume) following the intracardiac administration of 0.25 to 0.75 mg. of ouabain.

To account for the diminished output of normal hearts following digitalization, Dock and Tainter[92] concluded that digitalis caused a diminution in the venous return, probably by a constriction of the hepatic veins. This was based on the observations in dogs that digitalis caused not only a diminution in cardiac output but also a simultaneous reduction in venous pressure and an increase in the volume of the liver and of the portal venous pressure. However, an hepatic venoconstrictor (throttle) mechanism such as occurs in the dog could not be demonstrated in humans.[9]

McMichael and Sharpey Schafer[235] likewise concluded that digitalis exerted a peripheral venoconstrictor action in congestive heart failure, for the *increase* in cardiac output and fall in venous pressure mirrored closely similar changes produced by venesection or by the application of tourniquets. They concluded that digitalis, by causing venoconstriction, diminished the venous return and thus enabled the overloaded heart to contract more efficiently and augment its cardiac output. But with respect to congestive heart failure *the digitalis induced enhancement in cardiac* output and fall in venous pressure can be more satisfactorily explained by the direct myocardial action of digitalis with consequent improvement in cardiac contraction and emptying. With respect to the reported diminution in cardiac output following digitalization of normal hearts, it is probable that this is related to a reduction in blood volume and venous return, but it is unnecessary to assume a digitalis action on the peripheral veins. Here too a direct myocardial effect may be primary, with subsequent increase in renal excretion of sodium and water, diminution in blood volume and reduction in the venous return.

Circulating Blood Volume. Digitalis diminishes the circulating blood volume both in normal individuals[26] and in subjects with congestive heart failure.[101] We have seen that the increased blood volume in congestive heart failure results from renal retention of sodium and water which may serve as a compensatory mechanism to restore a deficient cardiac output. Digitalization, by improving cardiac contraction and cardiac output, reverses this series of events and diminishes the blood volume.

Venous Pressure. The venous pressure is

diminished after the administration of digitalis to patients with heart failure[101] This is best explained by improvement in cardiac contraction and emptying whereby the venous return is more effectively handled and damming of blood in the inflow veins to the failing chamber is eliminated In the observations of Bloomfield et al[32] an improvement in cardiac output preceded any fall in venous pressure In cases of isolated left ventricular failure Ferrer et al[1 0] observed that the administration of digoxin was followed by an augmented cardiac output and a sharply reduced pulmonary artery pressure but there was no effect on the central venous pressure

Circulation Time The circulation time of normal patients is not affected by digitalis But in patients with congestive heart failure the prolonged circulation time is diminished[316, 203]

Intracardiac and Pulmonary Blood Pressure In patients with right ventricular failure the right atrial pressure falls as does the venous pressure and the elevated right ventricular pressure diminishes[35, 166, 101] The pulmonary blood pressure when elevated by left-sided heart failure decreases after digitalization[204, 1 0] In cases of chronic pulmonary disease with right-sided heart failure the cardiac output increases and the right ventricular diastolic pressure falls after digitalis, but the pulmonary arterial blood pressure rises[1 0]

Digitalis and Electrolyte Excretion and Renal Function

Digitalis produces a prompt increase in the excretion of sodium and water in patients with congestive heart failure[117, 8] There is an enhanced renal plasma flow and glomerular filtration and a diminution in the filtration fraction and renal venous pressure However the improvement in excretion of sodium and water is not distinctly related to changes in glomerular filtration

INDICATIONS FOR DIGITALIS THERAPY

1 Congestive heart failure with regular sinus rhythm or with atrial fibrillation This is the primary indication for digitalis

2 Atrial fibrillation especially when the ventricular rate is rapid or congestive heart failure is present

3 Atrial flutter

4 Prevention and treatment of recurrent episodes of paroxysmal atrial tachycardia

Congestive Heart Failure

Digitalis is indicated primarily and most frequently in the treatment of congestive heart failure due to myocardial strain or impairment regardless of etiology Digitalis is indicated whether heart failure is mild or severe whether the rhythm is regular or irregular, whether the rate is rapid or not and whether or not heart block (unrelated to digitalis) is present In cases of heart failure in which some known remediable factor is the precipitating cause e g infection anemia hyperthyroidism correction of the precipitating factor may be more important but the administration of digitalis is also indicated at least until heart failure is abolished

Heart Failure with Atrial Fibrillation or Flutter The most dramatic therapeutic effects of digitalis are observed in cases of heart failure and atrial fibrillation especially when the ventricular rate is so rapid as to impair ventricular filling or cut into the recovery phase of diastole With digitalization ventricular rates of 120 to 150 may be rapidly reduced to 60 to 80 per minute and a pulse deficit is eliminated Concomitantly the manifestations of congestive heart failure such as dyspnea or venous engorgement are ameliorated or annulled If palpitation precordial distress or weakness is due to the rapid irregular ventricular rate these symptoms are relieved as the rate is slowed by digitalis

Digitalis should be administered to patients with congestive heart failure and atrial fibrillation even though the ventricular rate is not rapid The essential purpose of digitalization in cases of congestive heart failure is the improvement of the function of the myocardium and not the modification of the ventricular rate

Digitalis often exerts striking therapeutic effects in patients with heart failure and atrial flutter Frequently the digitalis not only slows the heart but converts the atrial flutter into atrial fibrillation Although stoppage of digitalis may be followed by restoration of regular rhythm this is unlikely to occur and the digitalis should not be discontinued for this purpose in cases of organic heart disease with enlarged hearts and chronic heart failure

Heart Failure with Sinus Rhythm The value of digitalis is usually less striking in cases of heart failure with regular rhythm than in those with atrial fibrillation, nevertheless its benefit is sufficiently clear[221, 171, 125, 120, 166]

Gavey and Parkinson[128] found digitalis efficacious in more than half of 47 cases of congestive heart failure with sinus rhythm and concluded that digitalis was indicated in the treatment of congestive heart failure irrespective of the rhythm. In many of the observations made in patients with heart failure and regular rhythm, digitalis reduced the cardiac rate without notable clinical benefit, in others clinical improvement occurred without a change in the heart rate, but in general clinical benefit and slowing of the heart occurred concomitantly. Flaxman[148] reported that digitalis was more effective in cases of heart failure with normal rate than in those with sinus tachycardia. He concluded that the beneficial action of digitalis was on the myocardium and not on the ventricular rate.

In a clinical study by Wood[361] digitalis effected demonstrable improvement in 18 of 20 patients with congestive heart failure and normal rhythm. Repeated determinations of the venous pressure were utilized to evaluate progress in his cases of right sided heart failure, and the arm to tongue circulation time in his cases of left heart failure. He likewise observed that a diminution in the cardiac rate was usually associated with improvement from digitalis therapy but in 2 cases there was no such alteration in rate despite distinct benefit. It is clear from these and other studies that digitalis produces clinical improvement in congestive heart failure by direct beneficial action on the heart muscle which is independent of its effect on cardiac rhythm or slowing of the cardiac rate.

The beneficial effect of digitalis is not limited to cases of right sided heart failure with venous congestion, hepatic enlargement and peripheral edema. Some of the most striking results are obtained in patients with isolated left sided failure[15, 16]. Thus dyspnea on exertion or at rest, orthopnea, cardiac asthma, nocturnal cough when due to the pulmonary congestion of heart failure are all indications for the administration of digitalis. In a series of cases of pure left sided heart failure Harrison, Calhoun and Furley[165] found that digitalis relieved the dyspnea and attacks of cardiac asthma and concomitantly increased the vital capacity and the speed of circulation.

Atrial Fibrillation (See also p 364)

Digitalis is most clearly indicated and is particularly beneficial in those cases of atrial fibrillation and rapid ventricular rate which are associated with congestive heart failure. Usually these are cases of coronary and hypertensive heart disease or of rheumatic heart disease with mitral stenosis. It is still a moot question whether the striking efficacy of digitalis in these cases is due exclusively or essentially to direct improvement in the efficiency of the failing myocardium[2, 203] or in large measure to indirect improvement mediated by impairment of atrioventricular conduction and consequent ventricular slowing. Digitalis does not abolish atrial fibrillation, in fact its direct or reflex effect on the vagus nerve by reducing the refractory period of atrial muscle, or its increase of atrial myocardial excitability, tends to perpetuate fibrillation (p 364).

When digitalis reduces the ventricular rate to between 60 and 80 per minute in cases of atrial fibrillation and heart failure it must be continued in the dosage necessary to maintain the desired ventricular rate and other clinical effects. However atrial fibrillation with normal or slow ventricular rate is sometimes encountered in the absence of heart failure. There are usually no symptoms and there is no indication for digitalis.

When atrial fibrillation with rapid ventricular rate is due to hyperthyroidism alone digitalis is not indicated unless there is evidence of heart failure. Neither is it indicated in the cases of atrial fibrillation due to a variety of less common causes of toxic, traumatic, infectious, neoplastic or other origin.

Atrial Flutter (See also p 357)

Digitalis is indicated in cases of congestive heart failure associated with atrial flutter, and in cases of atrial flutter with organic heart disease and pronounced enlargement of the atrium or ventricles. Digitalis is also indicated in cases of atrial flutter without heart failure or cardiac enlargement but its effectiveness is quite variable.

Digitalis may abolish atrial flutter but tends to convert it into atrial fibrillation by increasing the excitability of the atrial musculature. Large doses of digitalis are required and mild atrioventricular block may be produced. In most cases without serious organic heart disease, discontinuance of digitalis when atrial fibrillation has developed is followed by a reversion to regular sinus rhythm. But regular sinus rhythm may appear without the intermediary of atrial fibrillation and

without discontinuation of the digitalis If atrial flutter recurs repeatedly or if atrial fibrillation persists digitalis therapy may have to be continued in order to maintain optimal slowing of the ventricular rate In 100 cases of atrial flutter treated by digitalis Luckey [19] reported that normal sinus rhythm was established in 46 while digitalis was being continued in 32 the flutter was converted into atrial fibrillation with well controlled ventricular rate and in the remaining 22 atrial flutter persisted at a lower ventricular rate owing to a higher degree of block

Paroxysmal Tachycardia

The initial therapeutic measures recommended for the control of paroxysmal atrial tachycardia are discussed elsewhere (p 318) If carotid sinus pressure and induction of other vagal reflexes have failed to control an attack of paroxysmal tachycardia and especially if heart failure ensues digitalis may be given orally But many cardiologists employ a parenteral digitalis preparation as the initial form of therapy Preparations for intravenous injection (ouabain Cedilanid etc p 257) should be used if rapid action is important [107] Digitalis glycosides have also been recommended for prophylactic use in the prevention of recurrent paroxysmal arrhythmias

FACTORS MODIFYING THE INDICATIONS FOR DIGITALIS

Digitalis has been found to be more effective in certain cases of congestive heart failure or atrial fibrillation than in others Such apparent discrepancies will be clear if the actions of digitalis are kept in mind For digitalis can be beneficial only if the symptoms are due either to impaired myocardial *function which can still be helped by the drug* or to a rapid ventricular rate secondary to atrial fibrillation which can be slowed by impairing atrioventricular conduction Thus digitalis is ineffective in cases of cardiac failure due to *mechanical impediments* such as constrictive pericarditis extreme mitral stenosis or atrial thrombi occluding the mitral orifice It is also ineffective when myocardial damage is too severe or extensive to permit the heart muscle to respond to the medicament Digitalis is often of little help when the causative factor of heart failure is still active e g active rheumatic fever diphtheria Graves disease myxedema avitaminosis severe anemia or arteriovenous aneurysm In such cases medical or surgical elimination of the cause should be the essential element in therapy and digitalis only an accessory There is evidence that in various forms of high-output heart failure such as that due to hyperthyroidism beriberi and the like there is a metabolic impairment in energy formation in the heart muscle whereas in the more common low output heart failure the basic disturbance is in energy utilization [65] Since digitalis and related cardiac glycosides appear to improve energy utilization by the myocardium these drugs are of little or no value in forms of heart failure due exclusively or almost entirely to a defect in energy formation

CONTRAINDICATIONS AND NON INDICATIONS FOR DIGITALIS THERAPY

Arrhythmias and Tachycardias

Digitalis is not indicated for the treatment of tachycardias due to infections or fevers to hyperthyroidism drugs or neurocirculatory asthenia unless congestive heart failure is present Digitalis has been said to be contraindicated in the presence of premature contractions because of the danger of producing ectopic beats but the latter result only from toxic doses of the drug If cardiac failure appears the coexistence of premature beats does not contraindicate the use of digitalis Sometimes digitalis appears to dispel protracted premature beats with or without associated heart failure Similarly digitalis may occasionally terminate a prolonged paroxysmal tachycardia Digitalis is not indicated or contraindicated in the presence of ventricular tachycardia However if the patient also has congestive heart failure and is digitalized there is no need to discontinue digitalis unless there is a suspicion that the digitalis is responsible for the tachycardia Similarly digitalis may be given if the heart failure is the consequence of protracted ventricular tachycardia not due to digitalis [11] Other drugs should be given simultaneously to control the tachycardia (p 371)

Conduction Disturbances

Digitalis has frequently been said to be contraindicated in cases of *partial heart block* because of the danger of further impairment of atrioventricular conduction and the consequent *development* of complete heart block On the other hand Eggleston[29] obtained satisfactory results with the use of digitalis the block sometimes disappearing

when heart failure was relieved In a study of 19 patients with various grades of heart block, most of whom were suffering from congestive heart failure Blumgart and Altschule[85] administered digitalis in sufficient dosage to produce a therapeutic effect without observing any increase in the degree of block In some cases the P-R interval was shortened as the patient improved under digitalis therapy

In patients with *complete heart block*, digitalis is indicated only if there is congestive heart failure In the latter cases good therapeutic effects may be obtained with improved myocardial function The degree of block cannot be further increased However because of its vagal action digitalis may be undesirable in patients with frequent Adams-Stokes attacks or carotid sinus hypersensitivity[254]

Digitalis is not indicated in cases of sinus arrhythmia, sinoatrial block nodal rhythm or ventricular escape except when associated with heart failure These arrhythmias are often due to digitalis toxicity

Coronary Heart Disease

Coronary heart disease with angina pectoris or recent coronary occlusion is in itself neither an indication nor a contraindication to the use of digitalis Reports of the development or exacerbation of cardiac pain following the administration of digitalis[129] have led to hesitancy in using the drug in patients with angina pectoris for fear of causing vasoconstriction of the coronary arteries Freedberg and his associates[139] called attention to the similarity between the electrocardiographic changes associated with angina pectoris and those induced by digitalis But while the ST depressions observed with the former are related to subendocardial ischemia, the ST depressions caused by digitalis are due to another mechanism (p 270) There is no definite evidence that therapeutic doses of digitalis have a significant direct effect on coronary blood flow[113] Furthermore Gold Otto and associates[150] in a study of 120 patients with angina pectoris who were treated by alternating courses of digitalis and a placebo concluded that digitalis medication does not produce cardiac pain The beneficial effect of digitalis on the heart rate and efficiency of cardiac contraction in cases of heart failure should serve indirectly to promote the coronary blood flow, for the coronary flow is augmented in proportion to the work of the heart when the rate is slowed and the stroke volume increased (p 130) Digitalis should be given to patients with heart failure even if they suffer from angina pectoris

Similarly digitalis is not contraindicated if congestive failure develops in a patient with an acute coronary occlusion (coronary thrombosis) (p 579)

Shock and Infection

Digitalis is contraindicated in cases of central or peripheral circulatory failure associated with shock Digitalis further reduces the low blood volume and the insufficient output of the heart Postoperative shock is an example of a condition in which digitalis continues to be employed without benefit and probably with harm to the patient Digitalis is not indicated in cases of circulatory shock accompanying infections such as pneumonia or diphtheria A controlled study of a series of 834 cases of lobar pneumonia, in which alternate patients were given digitalis revealed a slightly higher mortality in the digitalized group[366] In cases of rheumatic fever digitalis is not indicated but when congestive heart failure appears the drug should be administered As a rule the benefits are not striking if there is rheumatic activity and large doses of the drug are required When shock and acute ventricular failure occur simultaneously in cases of acute myocardial infarction digitalis may be given and is sometimes of dramatic benefit if the left ventricular failure is a dominating element in the clinical picture

Surgical Procedures

Digitalis has been used extensively and unjustifiably in many patients who undergo surgical procedures There is no proof of its value preoperatively unless congestive failure is already present or unless the patient is subject to frequent attacks of paroxysmal atrial fibrillation, one of which may be precipitated by the operation Following operation, digitalis is not indicated either for cardiovascular collapse (shock) tachycardia or premature beats, all of which occur frequently

Hypertension and Nephritis

Hypertension is no contraindication to the use of digitalis in the treatment of heart failure An elevated blood pressure associated with heart failure (*Stauungshochdruck*) may fall when digitalis relieves the failure On the other hand cardiac failure may be accompanied by a fall in blood pressure which in

creases again when the heart recovers after digitalis therapy Digitalis is also well tolerated in patients with nephritis associated with congestive heart failure

Concomitant Drugs

Digitalis administration has been said to be dangerous or contraindicated in patients receiving calcium ephedrine or quinidine All of these drugs must be given with great care especially when administered intravenously to patients with heart failure But that their possible danger is due to synergism with digitalis is unproven neither is digitalis contraindicated when patients are receiving these drugs or vice versa

Compensated Heart Disease

I do not give digitalis prophylactically to patients with compensated heart disease unless digitalis was previously employed during heart failure

Toxic Symptoms

The chief contraindication to the administration of digitalis is the presence of symptoms due to overdosage of this drug (see p 264)

PREPARATIONS AND DOSAGE OF DIGITALIS

Powdered Whole Leaf

Until recently the powdered whole leaf of digitalis was the preparation recommended by the Digitalis Committee of the American Heart Association and it is probably still used widely It is a galenic preparation obtained from the dried leaves of Digitalis purpurea in the second year of growth of the plant and administered in the form of tablets capsules or tincture and rarely in suppositories or infusions The tablets pills and capsules usually contain 0 1 gm (1½ grains or 1 U S P unit) each and possess the advantage of accurate dosage and convenience of administration The tincture of digitalis which is a 10 per cent alcoholic solution of the leaf has also been used extensively and will not deteriorate for a long time if kept in a properly stoppered bottle Deterioration due to actinic rays is minimized by keeping the tincture in a brown bottle and by decolorizing with animal charcoal and adding aniline red [119] An accurate minim dropper is essential for measuring the dose

Dosage of Powdered Leaf of Digitalis The digitalizing dose is about 1 2 to 2 0 gm of U S P digitalis leaf or 12 to 20 cc of the tincture The subsequent maintenance dose is 0 1 to 0 15 gm or 1 0 to 1 5 cc of the tincture Details of digitalization and maintenance are discussed below

Absorption of digitalis leaf is relatively poor i e only about one fifth of the administered dose About 0 1 to 0 2 gm is excreted daily after full digitalization

Digilanid

Effective digitalis glycosides can be obtained from the leaf of Digitalis lanata as well as the more commonly employed Digitalis purpurea The essential ingredients of Digitalis lanata and their approximate proportions are lanatoside A—46 per cent lanatoside B—17 per cent lanatoside C—37 per cent Digilanid is a preparation of constant composition in which the impurities of the crude leaf have been removed and the pure active lanatosides A B and C have been combined in the above percentages It is provided in 0 33 mg tablets = 1 cat unit

Dosage of Digilanid The digitalizing oral dose ranges between 3 0 and 8 0 mg with daily doses of 0 33 mg for maintenance The intravenous digitalizing dose is 3 0 mg

Digitoxin and Other Pure Digitalis Glycosides

Digitoxin is a relatively pure crystalline digitalis glycoside isolated from digitalis leaf in a more purified form than the digitaline crystallisée of Nativelle Digitoxin gitoxin and gitalin are the glycosides obtainable from Digitalis purpurea leaf Digitoxin can also be obtained by hydrolysis of lanatoside A and gitoxin from lanatoside B of the Digitalis lanata leaf Lanatoside C yields digoxin which is unobtainable from Digitalis purpurea The chief advantage of digitoxin and other digitalis glycosides is their uniform and constant potency which makes it possible to administer them by weight and eventually dispense with biological assay The toxic symptoms of overdosage with cardiac glycosides are identical with toxic symptoms caused by the whole leaf preparations

Digitoxin is completely absorbed from the intestinal tract as indicated by the fact that the digitalizing dose is identical whether the drug is given orally or intravenously [111] There is no nausea or vomiting due to local gastric irritation but central nausea occurs with excessive dosage of digitoxin as with other digitalis preparations [112] The absence of gastrointestinal disturbance is attributed to freedom of the drug from irritating impurities rapid and complete absorption and the

minute dosage required for therapeutic effectiveness. Compared to other glycosides digitoxin has a relatively long latent period. Its activity begins one hour after intravenous administration and its maximum effect requires four hours or longer. The chief disadvantage is its long period of dissipation, two to three weeks being required for elimination. Studies on radioactive digitoxin administered to patients with heart failure indicate that unchanged digitoxin is excreted in the urine for as long as 40 days after the administration of a single dose.[57] Therefore when toxic symptoms appear they are relatively persistent. On the other hand, the slow elimination of digitoxin may also be considered an advantage because digitalization can be readily maintained for a long time.

Acetyldigitoxin is closely related chemically to digitoxin except for an acetyl group in its structure. It was reported to have the advantages of digitoxin but with less toxicity and somewhat faster dissipation. The digitalizing dose is 1.6 to 2.0 mg. and the maintenance dose 0.15 mg. (0.1-0.2 mg.)[21, 78]

Dosage of Digitoxin. The digitalizing dose was said to be 1.2 mg. when given in a single dose[144] but some patients require 2.0-2.5 mg.[33, 87, 117] I have repeatedly observed toxic symptoms with the lesser dose (1.2 mg.) but as a rule this dose is inadequate for digitalization. The average daily maintenance dose is stated to be 0.2 mg. but often 0.1 or 0.15 mg. or as little as 0.05 mg. suffice. It is apparent that digitoxin is approximately 1000 times as powerful as digitalis leaf, i.e., 0.1 mg. digitoxin = 0.1 gm. digitalis leaf.

Dogmatic oversimplification of dosage directions has lent unusual appeal to this preparation and has resulted on the one hand in inadequate digitalization in some patients, and on the other in toxic manifestations in other patients who require less than the recommended dose of 1.2 mg. Thus De Graff and his associates[87] found that only 17 per cent of patients were satisfactorily digitalized with 1.2 mg. of digitoxin, and that 1.7 mg. was the average single therapeutic dose. At the same time I have observed a pronounced increase in the occurrence of digitalis toxicity since digitoxin has been administered in the prescribed fixed dosage of 1.2 mg. for digitalization and 0.2 mg. daily for maintenance. In general, the recommended digitalizing dose of 1.2 mg. of digitoxin is inadequate, and the recommended maintenance dose of 0.2 mg. daily is excessive and eventually toxic. This high maintenance dose is responsible for the high incidence of toxic manifestations observed since the glycoside was recommended. Flaxman[116] recently reported 30 cases of digitoxin poisoning in patients who had taken the recommended doses of the drug. The earliest and commonest symptoms were disturbances in conduction including prolongation of the P-R interval and a-v dissociation. Master[9] described 9 cases of digitoxin poisoning with gastrointestinal and psychic symptoms, arrhythmias, atrial, nodal and ventricular tachycardia, partial and complete heart block and electrical alternans.

Digoxin

This is a pure crystalline glycoside derived from the leaves of Digitalis lanata and is closely related to lanatoside C. It is the one glycoside obtained from Digitalis lanata not obtainable from Digitalis purpurea. Like digitoxin it is a pure substance of definite and constant composition which can be prescribed in terms of weight of the pure drug. Its pharmacologic effects are identical with those of the whole leaf of digitalis or any of its glycosides.[78] A new related oral preparation, *acetyldigoxin*, obtained from lanatoside C, has recently been studied.[108, 215] The digitalizing dose is usually 2.0 to 5.0 mg., the maintenance dose 0.4 to 0.7 mg. daily.

According to De Graff,[85] digoxin, like digitoxin, is thoroughly and quickly absorbed from the gastrointestinal tract, but there is some uncertainty regarding this point. Digoxin is rapidly eliminated from the body which bears the advantage of less likely and briefer toxicity but also the disadvantage of greater difficulty in maintaining continuous digitalization. Elimination of a full digitalizing dose is complete in about 48 hours if no further digitalis has been given.[9] Therefore if there is uncertainty as to recent digitalis intake digoxin may be safer to administer than other digitalis preparations.

Dosage of Digoxin. The average digitalizing dose of digoxin given within 24 hours is about 3.75 mg. with a range of 2.0 to 5.0 mg.[85, 115] A dose of 1.5 mg. of digoxin usually produces a digitalizing effect in one or two hours and becomes maximal in six to eight hours. Additional doses of 0.25 mg. or 0.5 mg. may be given at [illegible] hour intervals to full digitalization. The daily maintenance dose

is 0.25 to 0.5 mg, occasionally only 0.125 mg, compared to 0.1 to 0.2 mg for digitoxin. Because of low solubility in water, digoxin is prepared for intravenous use in alcoholic solution, which must be diluted with saline before use. The intravenous dose is 0.75 to 1.0 mg, which produces an effect in 10 minutes and has maximal activity in one to two hours. In the rare instances in which digitalis must be given intravenously, other digitalis preparations are preferred (p. 262).

Gitalin

This is an amorphous, highly purified, water-soluble glycoside obtained from Digitalis purpurea and is the only glycoside obtained from Digitalis purpurea not also obtainable from Digitalis lanata. Gitalin, marketed as Gitaligin, is of uniform potency, is absorbed more rapidly and completely than digitalis leaf and is about 200 times as potent weight for weight. Its rate of elimination or dissipation (3 to 4 days) is equal to or slightly slower than that of digoxin, but more rapid than that of digitoxin. Its pharmacologic effects are virtually identical with those of the other digitalis glycosides and digitalis leaf. These similarities apply also to its toxic effects with excessive dosage.

Although gitalin has been available for a long time and its effectiveness reported for many years,[8, 2, 311] it has only recently attained a wide and enthusiastic following because of the claim that it has the widest range of safety (between its therapeutic and toxic doses) of any of the digitalis preparations. Thus Batterman and associates found that, whereas the ratio of the therapeutic to the toxic dose for digitoxin, digoxin and digitalis leaf, respectively, varied from 58 to 66 per cent,[8] the therapeutic to toxic dose ratio was only 37 per cent for gitalin.[14, 245] Furthermore, it has been claimed that gitalin may be effective when there is no further response to other digitalis preparations or when these had to be discontinued before therapeutic effectiveness because of toxic manifestations. If these claimed advantages are substantiated, gitalin would appear to be the most desirable digitalis preparation for oral use. That gitalin may be tolerated and prove effective when other digitalis preparations do not has been reported by other observers,[172, 85] but Hejmancik and Herrmann[173] could not confirm the wide therapeutic ratio reported by Batterman et al.[14] In general I am skeptical of claims of less toxicity of one digitalis preparation compared to another when comparative dosage and therapeutic effects are considered. There are obvious difficulties in quantitative titration of digitalis preparations in dealing with human patients and especially in trying to distinguish therapeutic effects, toxic effects and manifestations of heart failure itself.

Dosage of Gitalin (Gitaligin). The average digitalizing dose has been variously found to be 5.0 to 6.5 mg,[14, 164] but the range is between 3.0 and 10.5 mg. The maintenance dose is most commonly 0.25 to 0.5 mg and occasionally 0.75 mg to 1.0 mg daily. Gitalin may be administered intravenously, its digitalizing dose being identical with that when given orally,[163] namely, 2.5 mg to 3 mg initially and repeated in 24 hours. Maintenance is by two injections of 2.5 mg weekly. For rapid oral digitalization 5 tablets (2.5 mg) of Gitaligin are administered at once, then 1½ tablets (0.75 mg) of Gitaligin are given every six hours. Digitalization is thus effected in 24 to 36 hours. For slow digitalization 3 tablets (1.5 mg) are administered daily for four to six days.

Lanatoside C

Lanatoside C, marketed under the trade name of Cedilanid, is an initial crystalline glycoside related to digoxin and likewise derived from Digitalis lanata leaf. Compared with the other two commonly employed glycosides already discussed, lanatoside C has the shortest latent period and the most rapid elimination. The speed of elimination makes it less satisfactory than digitoxin for oral use because it is difficult to maintain digitalization and relatively high initial dosage is required. On the other hand, the brief latent period makes lanatoside C desirable for intravenous administration.[107, 215] Slowing of a rapid ventricular rate in atrial fibrillation may be effected within ten minutes to two hours after intravenous administration. As a rule its effect is maximal within 60 minutes. Its effect persists 12 to 36 hours and disappears in three to six days.[107] In summary, lanatoside C is more rapid in its effect than digitoxin, slightly more rapid than digoxin, but slower than ouabain (below). Therefore it is not as immediately effective as the latter for urgent intravenous use, but the duration of its effect is longer.

Dosage of Lanatoside C. The average oral

minute dosage required for therapeutic effectiveness. Compared to other glycosides digitoxin has a relatively long latent period. Its activity begins one hour after intravenous administration and its maximum effect requires four hours or longer. The chief disadvantage is its long period of dissipation, two to three weeks being required for elimination. Studies on radioactive digitoxin administered to patients with heart failure indicate that unchanged digitoxin is excreted in the urine for as long as 40 days after the administration of a single dose. Therefore, when toxic symptoms appear they are relatively persistent. On the other hand, the slow elimination of digitoxin may also be considered an advantage because digitalization can be readily maintained for a long time.

Acetyldigitoxin is closely related chemically to digitoxin except for an acetyl group in its structure. It was reported to have the advantages of digitoxin but with less toxicity and somewhat faster dissipation. The digitalizing dose is 1.6 to 2.0 mg. and the maintenance dose 0.15 mg. (0.1–0.2 mg.).[15, 7, 8]

Dosage of Digitoxin. The digitalizing dose was said to be 1.2 mg. when given in a single dose,[144] but some patients require 2.0–2.5 mg.[2, 3, 27, 317] I have repeatedly observed toxic symptoms with the lesser dose (1.2 mg.) but as a rule this dose is inadequate for digitalization. The average daily maintenance dose is stated to be 0.2 mg., but often 0.1 or 0.15 mg. or as little as 0.05 mg. suffices. It is apparent that digitoxin is approximately 1000 times as powerful as digitalis leaf, i.e., 0.1 mg. digitoxin = 0.1 gm. digitalis leaf.

Dogmatic oversimplification of dosage directions has lent unusual appeal to this preparation and has resulted on the one hand in inadequate digitalization in some patients, and on the other in toxic manifestations in other patients who require less than the recommended dose of 1.2 mg. Thus De Graff and his associates[87] found that only 17 per cent of patients were satisfactorily digitalized with 1.2 mg. of digitoxin and that 1.7 mg. was the average single therapeutic dose. At the same time I have observed a pronounced increase in the occurrence of digitalis toxicity since digitoxin has been administered in the prescribed fixed dosage of 1.2 mg. for digitalization and 0.2 mg. daily for maintenance. In general, the recommended digitalizing dose of 1.2 mg. of digitoxin is inadequate, and the recommended maintenance dose of 0.2 mg. daily is excessive and eventually toxic. This high maintenance dose is responsible for the high incidence of toxic manifestations observed since the glycoside was recommended. Flaxman[16] recently reported 30 cases of digitoxin poisoning in patients who had taken the recommended doses of the drug. The earliest and commonest symptoms were disturbances in conduction including prolongation of the P-R interval and a-v dissociation. Master[9] described 9 cases of digitoxin poisoning with gastrointestinal and psychic symptoms, arrhythmias, atrial, nodal and ventricular tachycardia, partial and complete heart block and electrical alternans.

Digoxin

This is a pure crystalline glycoside derived from the leaves of Digitalis lanata and is closely related to lanatoside C. It is the one glycoside obtained from Digitalis lanata not obtainable from Digitalis purpurea. Like digitoxin it is a pure substance of definite and constant composition which can be prescribed in terms of weight of the pure drug. Its pharmacologic effects are identical with those of the whole leaf of digitalis or any of its glycosides.[278] A new related oral preparation, *acetyldigoxin*, obtained from lanatoside C, has recently been studied.[103, 215] The digitalizing dose is usually 2.0 to 5.0 mg., the maintenance dose 0.4 to 0.7 mg. daily.

According to De Graff[85] digoxin, like digitoxin, is thoroughly and quickly absorbed from the gastrointestinal tract, but there is some uncertainty regarding this point. Digoxin is rapidly eliminated from the body, which bears the advantage of less likely and briefer toxicity, but also the disadvantage of greater difficulty in maintaining continuous digitalization. Elimination of a full digitalizing dose is complete in about 48 hours if no further digitalis has been given.[9] Therefore if there is uncertainty as to recent digitalis intake digoxin may be safer to administer than other digitalis preparations.

Dosage of Digoxin. The average digitalizing dose of digoxin given within 24 hours is about 3.75 mg. with a range of 2.0 to 5.0 mg.[85, 113] A dose of 1.5 mg. of digoxin usually produces a digitalizing effect in one or two hours and becomes maximal in six to eight hours. Additional doses of 0.25 mg. or 0.5 mg. may be given at 4 hour intervals to full digitalization. The daily maintenance dose

is 0.25 to 0.5 mg., occasionally only 0.125 mg., compared to 0.1 to 0.2 mg. for digitoxin. Because of low solubility in water, digoxin is prepared for intravenous use in alcoholic solution which must be diluted with saline before use. The intravenous dose is 0.75 to 1.0 mg., which produces an effect in 10 minutes and has maximal activity in one to two hours. In the rare instances in which digitalis must be given intravenously, other digitalis preparations are preferred (p. 262).

Gitalin

This is an amorphous, highly purified water-soluble glycoside obtained from Digitalis purpurea and is the only glycoside obtained from Digitalis purpurea not also obtainable from Digitalis lanata. Gitalin, marketed as Gitaligin, is of uniform potency, is absorbed more rapidly and completely than digitalis leaf and is about 200 times as potent weight for weight. Its rate of elimination or dissipation (3 to 4 days) is equal to or slightly slower than that of digoxin but more rapid than that of digitoxin. Its pharmacologic effects are virtually identical with those of the other digitalis glycosides and digitalis leaf. These similarities apply also to its toxic effects with excessive dosage.

Although gitalin has been available for a long time and its effectiveness reported for many years[8-11] it has only recently attained a wide and enthusiastic following because of the claim that it has the widest range of safety (between its therapeutic and toxic doses) of any of the digitalis preparations. Thus Batterman and associates found that whereas the ratio of the therapeutic to the toxic dose for digitoxin, digoxin and digitalis leaf respectively varied from 58 to 66 per cent,[9] the therapeutic to toxic dose ratio was only 37 per cent for gitalin.[10, 310] Furthermore, it has been claimed that gitalin may be effective when there is no further response to other digitalis preparations or when these had to be discontinued before therapeutic effectiveness because of toxic manifestations. If these claimed advantages are substantiated, gitalin would appear to be the most desirable digitalis preparation for oral use. That gitalin may be tolerated and prove effective when other digitalis preparations do not has been reported by other observers[173, 89] but Hejmancik and Herrmann[173] could not confirm the wide therapeutic ratio reported by Batterman et al.[10] In general I am skeptical of claims of less toxicity of one digitalis preparation compared to another when comparative dosage and therapeutic effects are considered. There are obvious difficulties in quantitative titration of digitalis preparations in dealing with human patients, and especially in trying to distinguish therapeutic effects, toxic effects and manifestations of heart failure itself.

Dosage of Gitalin (Gitaligin). The average digitalizing dose has been variously found to be 5.0 to 6.5 mg.[10, 183, 89] but the range is between 3.0 and 10.5 mg. The maintenance dose is most commonly 0.25 to 0.5 mg. and occasionally 0.75 mg. to 1.0 mg. daily. Gitalin may be administered intravenously, its digitalizing dose being identical with that when given orally,[183] namely 2.5 mg. to 3 mg. initially and repeated in 24 hours. Maintenance is by two injections of 2.5 mg. weekly. For rapid oral digitalization 5 tablets (2.5 mg.) of Gitaligin are administered at once, then 1½ tablets (0.75 mg.) of Gitaligin are given every six hours. Digitalization is thus effected in 24 to 36 hours. For slow digitalization 3 tablets (1.5 mg.) are administered daily for four to six days.

Lanatoside C

Lanatoside C, marketed under the trade name of Cedilanid, is an initial crystalline glycoside related to digoxin and likewise is derived from Digitalis lanata leaf. Compared with the other two commonly employed glycosides already discussed, lanatoside C has the shortest latent period and the most rapid elimination. The speed of elimination makes it less satisfactory than digitoxin for oral use, because it is difficult to maintain digitalization and relatively high initial dosage is required. On the other hand the brief latent period makes lanatoside C desirable for intravenous administration.[307, 333] Slowing of a rapid ventricular rate in atrial fibrillation may be effected within ten minutes to two hours after intravenous administration. As a rule its effect is maximal within 60 minutes. Its effect persists 12 to 36 hours and disappears in three to six days.[307] In summary, lanatoside C is more rapid in its effect than digitoxin, slightly more rapid than digoxin, but slower than ouabain (below). Therefore it is not as immediately effective as the latter for urgent intravenous use, but the duration of its effect is longer.

Dosage of Lanatoside C. The average oral

digitalizing dose of lanatoside C is 7 5 mg (5 0 to 10 0 mg) within 24 hours[143, 307] Maintenance dose is 1 0 to 1 5 mg daily For rapid intravenous digitalization the dose is 0 8 mg to 1 6 mg lanatoside C, given slowly or in divided doses every four hours until the desired effect is attained The maintenance dose intravenously is 0 4 mg every six hours Lanatoside C is available commercially as Cedilanid in tablets of 0 5 mg and in ampules of 2 cc containing 0 4 mg and in ampules of 4 cc containing 0 8 mg See also page 263

Ouabain and Other Strophanthins

A number of glycosides have been isolated from Strophanthus kombé and Strophanthus gratus[197] The most important of these is ouabain, a pure crystalline substance derived *from the latter Both ouabain and the various* K strophanthins now available, are poorly absorbed from the gastrointestinal tract and therefore unsuitable for oral use K Strophanthoside is available commercially as Strophosid in 0 5 cc ampules containing 0 25 mg and in 1 cc ampules *containing 0 5 mg* The initial intravenous dose is 0 3 mg administered slowly to patients who have not received digitalis, and 0 15 or 0 3 mg may be given again after 24 hours

Ouabain (G strophanthin) is the drug of choice for emergency intravenous use because of its very brief latent period [redacted] A reduction in ventricular rate and venous pressure may be attained within five minutes after injection with a maximum effect in 30 to 120 minutes and a duration of 24 to 72 hours[143] *Its rapid* elimination makes ouabain unsatisfactory for *maintenance of digitalization* Therefore the combined use of ouabain intravenously for rapid immediate effect with digitalis preparations orally for subsequent maintenance has been recommended[11] *Acetylstrophanthidin* acts even more rapidly than ouabain producing its full effect in ten minutes as compared to one hour for the latter Ouabain is available in 0 5 cc ampules containing 0 1 mg, and 2 cc *ampules containing 0 5 mg* Acetylstrophanthidin is available in 1 cc *ampules* containing 0 6 mg (For dosage and administration of ouabain and acetylstrophanthidin, see p 262)

Other Digitalis like Preparations—Squill

Glycosides of squill also have a satisfactory digitalis like action and have been used therapeutically The commercial preparation Scillaren contains 2 parts *crystalline scillaren* A and one part of amorphous scillaren B One commercial preparation urginin (Urginea Indica) has two water insoluble glycosides urginin A and B, while another urginin (from Urginea Maritima) contains equal mixtures of scillaren A and B The digitalizing dose is 9 0 to 14 0 mg for scillaren and 4 0 to 6 0 mg for urginin The daily maintenance dose is about 0 8 mg for urginin and 1 6 mg for scillaren

Still other preparations with a digitalis like action, but not recommended for clinical use *include cymarin from apocynum, thevetin, a* cardiac glycoside obtained from the nuts of the be-still plant, convallaria, and folinerin—a crystallized glucoside from the Nerium oleander Analyses of the various commercial *preparations and their therapeutic effects* have been reported by Stroud and Vander Veer,[323] De Graff[85] and Freedberg and Zoll[130]

STANDARDIZATION AND ASSAY OF DIGITALIS PREPARATIONS

According to U S Pharmacopoeia XIV the potency of digitalis is such that when assayed as directed 0 1 gm shall be equivalent to not less than 1 0 U S P digitalis unit One U S P digitalis unit represents the potency of 0 1 gm of the U S P Reference Standard This latter in turn is standardized according to a standard international reference powder of digitalis of the World Health Organization of the United Nations In actual usage digitalis preparations for intravenous injection con*taining a given number of digitalis units may* have a much greater pharmacologic effect than digitalis leaf preparations with the same number of units administered orally This is largely due to less and variable absorption from the gastrointestinal tract of the oral preparations

The pure glycosides such as digoxin and digitoxin are standardized by weight with the aid of *colorimetric techniques Digitalis leaf* preparations are assayed by biologic tests Formerly the frog method was official, a frog unit being defined as the amount of digitalis per gram of frog weight, which when injected into the ventral lymph sac of male frogs (20 to 30 gm) produced permanent systolic stand still in one hour at room temperature Later the cat method was used The amount of *dissolved drug, injected intravenously*, necessary to cause cessation of the cat's heart beat was compared with the amount of the

standard necessary to produce this lethal effect At present pigeons are employed for assay, the material tested being compared with a standard preparation as to the quantity necessary to produce fatal cardiac arrest on intravenous administration The potency of the assayed preparation is expressed in U S P units per cc

This method of assay is far from ideal and does not accurately and consistently measure the effect of the drug as given to humans by mouth and in therapeutic doses as contrasted with its assay in animals given intravenously and in lethal doses Gold[141] showed that a variety of digitalis preparations of identical potency in cat units exhibited a ten fold range of activity in humans Assay in humans by electrocardiographic modification has been attempted but is still unsatisfactory [339] Chemical and colorimetric assays have likewise failed to yield consistent results or reliable measurements of therapeutic activity in humans [78]

THE ADMINISTRATION OF DIGITALIS

Modern concepts of adequate digitalis dosage are based on the detailed studies of Eggleston[95] with standardized digitalis preparations For a long time inadequate doses were utilized with unsatisfactory effects despite Withering's[345] admonition that the drug be continued until it acts either on the kidneys the stomach the pulse or the bowels let it be stopped upon the first appearance of any one of these effects On the other hand it is usually possible to obtain a satisfactory therapeutic effect without quite causing the symptoms mentioned by Withering for these symptoms are evidences of overdosage *The fundamental principle of digitalization is to administer the drug until the desired therapeutic effect is achieved or toxic symptoms appear* But it is rarely necessary to induce toxic manifestations

Choice of Digitalis Preparation

Effective digitalization can be attained by any of the preparations listed The physician should be thoroughly familiar with at least one preparation for intravenous use in order to obtain very rapid digitalization and one preparation for oral slower action At present there is ouabain or Cedilanid for intravenous use gitalin digoxin digitoxin or digitalis leaf for oral use Intravenous administration has no more beneficial effect on myocardial function than oral administration Neither is one oral preparation more effective than another when the proper dosages are administered The essential differences concern the speed of action and the time required for dissipation and elimination

The technique of administering digitalis includes (1) the induction of digitalization rapidly or slowly until the desired therapeutic effect is obtained without symptoms of overdosage and (2) subsequent maintenance of digitalization so that the benefits of the drug are retained continuously as long as necessary

Methods of Inducing Digitalization (Oral Methods)

Although the total dose necessary to obtain a maximum therapeutic effect without toxic symptoms varies from patient to patient and even in the same patient at different times Eggleston[95] has shown that this dose can be predicted approximately from the weight of the patient Allowance must be made for the amount of digitalis eliminated or destroyed by the body during the period in which digitalization is induced Therefore a larger total dosage is required to digitalize a patient in one or two weeks than to digitalize him in one or two days

In practice we have learned the approximate oral digitalizing dose for the various digitalis preparations and this amount is given in single or divided amounts within the period to be allowed for digitalization

The average digitalizing doses (within 24 to 48 hours) for the commonly employed digitalis preparations are

Oral	*Average*	*Usual Range*
Digitalis leaf	1 8 gm	1 2 to 2 0 gm
Tincture of digitalis	18 cc	12 to 20 cc
Digitoxin	1 8 mg	1 2 to 2 0 mg
Digoxin	3 75 mg	2 0 to 5 0 mg
Gitalin	5 5 mg	3 to 10 5 mg
Lanatoside C	7 5 mg	5 to 10 mg

Very large persons may require more and small or aged persons somewhat less Larger doses of digitalis than the above-stated average may be necessary to attain a satisfactory therapeutic effect in patients with very severe congestive heart failure and when failure is associated with active rheumatic fever infections or hyperthyroidism Children above the age of four have been found by McCulloch and Rupe[23] to require considerably more digitalis per body weight than the

doses given above for adults; Sutton and Wyckoff[34] however, found no essential difference in their study on the treatment of children with rheumatic heart disease (See p 261 for digitalization in children)

The important point to remember is that the above doses are practical average figures which may require considerable modification in individual cases Much larger doses may have to be administered if a satisfactory therapeutic effect is not obtained or the drug may have to be stopped before the full estimated dose is given if more than mild symptoms of digitalis intoxication appear Two weeks are usually required for the elimination of digitalis from the body If digitalis has been administered in the preceding two weeks and further digitalization appears necessary the amount remaining may possibly be calculated and subtracted from the dose that would have been given if the patient were digitalis free But if there is any doubt it is safer to digitalize slowly by administering digitalis leaf powder 0 1 gm every six hours and observe the patient carefully for therapeutic or toxic effects Because of their speedier elimination lanatoside C (Cedilanid) 1 mg three times a day or digoxin 0 5 mg three times a day may be preferable in these circumstances

The speed with which digitalization is induced depends on the urgency of the patient's clinical condition The following oral methods have been found practical but they may be modified

Rapid Digitalization in 12 to 36 Hours This method applies to patients with acute congestive heart failure especially when caused by a paroxysm of atrial fibrillation with extremely rapid ventricular rate, to patients with acute left ventricular failure and to patients with severe chronic congestive heart failure When digitalization is required within four hours or less intravenous therapy should be employed (p 262) However Evans et al[115] have found 2 to 3 mg of digoxin, given orally satisfactory for digitalization in four hours Rapid oral digitalization may also be effected by digitoxin A single dose of 1 5 mg often effects digitalization in six hours but this initial dose may produce toxic symptoms It is important to avoid rapid digitalization when slower methods suffice as they do in the vast majority of cases of heart failure The following table represents the usual initial and subsequent doses for rapid digitalization (24 hours) with various digitalis preparations

Oral	*Initial dose*	*Dose every 8 hours thereafter until digitalization*
Digitalis leaf	0 8 gm	0 2 gm
Digitoxin	0 8 mg	0 2 mg
Digoxin	1 5 mg	0 5 mg
Gitalin	2 5 mg	0 75 mg
Lanatoside C	3 0 mg	1 0 mg
Tincture of digitalis	8 0 cc	2 0 cc

Digitalization in Three Days This method is useful for patients with well developed but not urgent signs of congestive heart failure Digitalization can be accomplished fairly rapidly at the same time that toxicity is more readily avoided because it is easier to stop short of excessive dosage A dose of 0 2 gm of powdered digitalis leaf (or 0 2 mg digitoxin or 0 5 mg digoxin or 0 75 mg gitalin) is given three times daily for two or three days If the rapidly excreted digoxin or lanatoside C is used it is preferable to give the total daily dose in the morning instead of dividing it into three doses per day Thereafter dosage is determined by therapeutic effect or the development of toxicity

Slow Digitalization in One Week This method is practical for mild or moderately decompensated patients for ambulant patients examined only in the office or hospital outpatient department who are not likely to be seen oftener than once a week, and for patients with uncertain amounts of unexcreted digitalis Either 0 1 gm of powdered leaf or 1 cc of the tincture is given three times daily or 0 3 mg digitoxin or 0 75 mg of digoxin or 1–1 5 mg of gitalin or 1 5 mg of lanatoside C is given in a single daily dose until the desired therapeutic effect is achieved or toxic manifestations supervene Many patients will require continuation or elevation of this dosage, as determined by the clinical status at the end of a week In other cases the dosage may be reduced to the level necessary for maintenance

Criteria of Therapeutic Effect Having carried out one of the above schedules of dosage the physician must determine whether satisfactory digitalization has actually been attained i e, whether the patient has had a maximum therapeutic response If not and regardless of the dosage already administered, the recommended dose of digitalis

should be continued until adequate benefit is secured or toxic symptoms appear

In patients with atrial fibrillation and a rapid ventricular rate slowing of the heart and elimination of a pulse deficit are approximate criteria of favorable digitalis effects As a rule the heart rate is slowed to 70 to 80 per minute but some patients are comfortable only if the resting cardiac rate is slowed to about 60 for it may rise considerably with slight activity On the other hand it is not safe to continue digitalis until such slowing is obtained without regard to other manifestations for digitalis intoxication may occur while the heart rate is still relatively rapid However even slower rates may be safely achieved if there are no toxic signs or symptoms Furthermore a rapid pulse rate may be misleading when due to ventricular extrasystoles resulting from digitalis intoxication For the rapid rate may be interpreted as indicating that the patient's condition is worse and that he is in need of larger doses of digitalis Therefore the cardiac and pulse rates are guides to the administration of digitalis only when considered in connection with the patient's clinical course as regards both the symptoms of heart failure and those of digitalis overdosage (p 264)

In patients with regular rhythm a satisfactory therapeutic effect of digitalis is indicated by relief of dyspnea orthopnea or cardiac asthma by diuresis and loss of edema disappearance of rales at the bases of the lungs and a diminution in the venous pressure and circulation time Although there is no doubt of the benefit of digitalis in heart failure with regular sinus rhythm its therapeutic accomplishment is rarely as striking as in heart failure with atrial fibrillation and a rapid ventricular rate I therefore rarely use intravenous digitalization in patients with sinus rhythm and try to avoid haste and excessive dosage For one is most apt to induce digitalis toxicity in these patients with sinus rhythm because the clinical criteria for digitalization are more difficult to evaluate than the criterion of ventricular rate in cases with atrial fibrillation Persistence of the clinical manifestations of heart failure is commonly due to the complicating factors or incomplete or improper use of other therapeutic agents and not necessarily to inadequate digitalization Therefore one should be very cautious in pressing digitalization after one has administered an average dose in patients with sinus rhythm

Maintenance of Digitalization

When the optimal response has been obtained it is important to maintain a continued state of therapeutic digitalis saturation by administering smaller doses of medicament to compensate for the amount excreted or destroyed by the body According to Gold and De Graff[14] the patient does not excrete a fixed amount of drug each day but a fraction of the amount present in the body Thus 0 2 gm of digitalis may be excreted daily and may have to be administered daily to maintain digitalization after the patient has been digitalized with 1 5 gm of digitalis leaf However if the patient has received no digitalis previously a daily dose of 0 2 gm may be cumulative and eventually effect digitalization

In practice the daily maintenance doses for the common digitalis preparations are

Digitalis leaf	0 1 gm (0 05 to 0 15 gm)
Tincture of digitalis	1 0 cc (0 5 to 1 5 cc)
Digitoxin	0 1 mg (0 05 to 0 2 mg)
Digoxin	0 25 mg (0 125–0 75 mg)
Gitalin	0 5 mg (0 25–1 0 mg)
Lanatoside C	1 0 mg (0 5–1 5 mg)

As with the initial digitalizing dose the maintenance dose must be adjusted to the individual and his clinical response The above doses are approximations to be used as guides It should be emphasized that most patients with congestive heart failure will require maintenance doses of digitalis for the balance of their life

If symptoms of digitalis intoxication appear either during the induction or maintenance of digitalization the drug should be discontinued until the toxic symptoms disappear and for one to two days thereafter Digitalis may then be resumed in smaller dosage It should be recognized however that in patients with severe congestive heart failure the optimal therapeutic and the toxic dose are sometimes very close In ambulant patients with mild congestive heart failure there is a wide margin between the therapeutic and toxic doses and an optimal clinical result should be obtained with smaller doses and therefore without toxic symptoms[15]

Digitalization of Children

Heart failure in children is usually due to rheumatic fever and rheumatic cardiovalvular

disease, occasionally to congenital heart disease Persistent rheumatic activity with acute and subacute carditis is the rule in the rheumatic cases of heart failure and this prevents or obscures the therapeutic efficacy of digitalis This may be the reason for the frequent statement that children require 50 to 100 per cent more digitalis per pound of body weight than do adults[2] Similarly pronounced arterial anoxemia in children with congenital heart disease and heart failure impairs the therapeutic action of digitalis On the basis of the dosage of digitalis producing RS-T wave changes in the electrocardiogram Mathes and associates[30] found that children were more tolerant to digitoxin than were adults when the digitoxin was given orally in the same dose per unit weight But the differences appeared small and of questionable practical significance Nevertheless the authors concluded that children required about 50 per cent more digitoxin by body weight than adults Crawford et al[72] suggested that digitalis dosage should be determined according to surface area, and explained the higher digitalis dosage required by children as due to a relatively larger surface area per unit of weight

To avoid the toxic symptoms which occur with disproportionate frequency in digitalized children, very rapid digitalization should be shunned, and dosage should be gauged by therapeutic effect rather than by arbitrary calculation For children weighing between 50 and 100 pounds one-half the adult dose may be used as an approximate amount for initial digitalization, below 50 pounds one sixth to one quarter the adult dose should be given Taussig[7] recommended digitalization by administering 0 1 gm (1½ grains) of digitalis leaf three times daily until optimal therapeutic effect is obtained or toxic symptoms appear She then advised a maintenance dose of 0 05 to 0 1 gm (¾ to 1½ grains) daily, with complete omission of the drug for one or two days each week Rosenbaum and associates[240] administered 0 02 to 0 025 mg digitoxin per pound to children more than two years of age and 0 01 to 0 02 mg to children less than two over a period of 24 hours for digitalization, or more rapidly in emergencies One tenth of the digitalizing dose was given daily orally for maintenance of digitalization Using this dosage schedule in 41 infants and children in congestive heart failure Nadas et al[25] observed the most satisfactory response when the heart failure was due to myocardial disease, paroxysmal tachycardia or rheumatic carditis and the least satisfactory when it was due to congenital heart disease especially with cyanosis If the above mentioned dosage schedule is used with other digitalis preparations, the following equivalents may be useful approximations 0 1 gm digitalis leaf, 0 1 mg digitoxin, 0 25 mg digoxin, 0 5 mg gitalin For emergency digitalization of children Cedilanid may be given intravenously but slowly in a total dose of 0 02 mg per pound body weight or in fractional doses provided no digitalis has been given in the previous two weeks

Intravenous Administration of Digitalis or Strophanthin (Ouabain) Intramuscular Digitalization

The intravenous administration of digitalis is indicated only in emergencies requiring digitalization within a few hours This might be necessary for patients with acute congestive heart failure due to an attack of paroxysmal atrial fibrillation with very rapid ventricular rate, patients with acute congestive heart failure or myocardial infarction and massive pulmonary edema, undigitalized patients with chronic congestive heart failure who are moribund, or in patients developing heart failure during operations[153] As a rule however sufficiently rapid digitalization can be obtained by the oral route Sometimes intravenous digitalization is employed when the patient cannot take oral medication because of vomiting, as in patients who have recently undergone surgery, or because of coma Ouabain or digitalis preparations should not be given intravenously if the patient has received a digitalis preparation in the preceding two weeks In general the intravenous administration of digitalis or strophanthin is rarely essential If there is no emergency but digitalis must be administered parenterally because the patient cannot take oral medication, digitoxin and other digitalis preparations may be administered intramuscularly[2,1] The dose time of onset and peak action of intravenously administered digitalis and strophanthin preparations are shown in Table 8

When intravenous digitalization is necessary, ouabain, the crystallized glycoside from

Table 8 Dosage and Time of Action of Intravenously Administered Digitalis Glycosides

DRUGS	INITIAL DOSE mg	ONSET OF ACTION	PEAK ACTION	REGRESSION AND DISSIPATION
Acetylstrophanthidin	0.3–0.6	1–5 min	10–15 min	4 hr
Ouabain	0.25–0.5	3–10 min	½–2 hr	12 hr–3 days
Strophanthin K (Strophosid)	0.3–0.6	10–15 min	1–2 hr	1–5 days
Lanatoside C (Cedilanid)	0.8	10–30 min	1–3 hr	1–6 days

Note Total digitalizing dose is usually twice the initial dose

G strophanthus is preferred to digitalis preparations because of its more rapid action (five to forty five minutes as compared to two or three hours) Furthermore the effect of ouabain is dissipated more rapidly (one to two days as compared to one to three weeks for digitalis) There has been some fear of using strophanthin and ouabain which are powerful poisons (used long ago as arrow poisons) and which can produce premature beats ventricular tachycardia or fibrillation and death within a half hour after injection But it is doubtful whether the relation of therapeutic to toxic dose for ouabain is different from that of the digitalis glycosides Most of the reported accidents may have been due to previous digitalization with incomplete elimination at the time ouabain was injected or to overdosage

Wyckoff and Goldring[307] administered ouabain intravenously in patients with atrial fibrillation and rapid ventricular rate with good therapeutic results and without dangerous incidents The full therapeutic dose was found to be 1 mg for 150 pounds of body weight *A total dosage of 1 mg of ouabain should not be exceeded in a 24 hour period* *It should not be given at all if digitalis has been administered in the preceding two weeks* Wyckoff and Goldring[307] gave an initial dose of 0.5 mg followed by injections of 0.1 mg every half hour until a satisfactory therapeutic or toxic effect was obtained A maximum action was usually observed in less than an hour Slowing of the heart thus obtained persisted for five days or less While I have found this dosage schedule to be a safe one some physicians prefer to proceed more cautiously with an initial dose of 0.25 mg of ouabain followed by injections of 0.1 mg at half hour intervals until effective The drug should be administered slowly Another procedure is to give 0.25 to 0.5 mg of ouabain intravenously in a single dose and simultaneously 0.6 mg of digitoxin or 1.5 mg of digoxin orally to continue digitalization or digitalis leaf can be given in 0.2 gm doses every six hours until digitalization is effected According to this regime the intravenous injection is utilized only for a speedy start but is not repeated If digitalization is effected intravenously and no further digitalis is given for several days it is not necessary to repeat digitalization provided the therapeutic effect has persisted One may maintain digitalization with ordinary maintenance doses Although the intravenous drug is rapidly dissipated its therapeutic effect may persist several days longer

Acetylstrophanthidin is a partial synthetic which has almost an immediate digitalis like action Its full effect is attained in 10 to 15 minutes and wears off in four to five hours There is some question as to the difficulty in controlling its dose and the consequent danger of toxicity[316] There are several reports as to the value of this drug[107, 153] but the occurrence of ventricular fibrillation has been noted following its administration[61] It is about half as potent as ouabain and its digitalizing dose is 1 to 2 mg The initial dose is 0.6 mg intravenously administered very slowly and 0.2 mg at 20 to 30 minute intervals until digitalization is effected

Of the various digitalis preparations probably lanatoside C is the most desirable for intravenous use because it is a pure crystalline substance of constant composition and because it has the briefest latent period and the most rapid rate of elimination of the commonly available digitalis glycosides Lanatoside C is marketed as Cedilanid in 2 cc and 4 cc ampules containing *0.2 mg per cc* Sokolow and Chamberlain[307] used it in doses up to 14 cc per day in 38 cases In general 8 cc was the digitalizing dose and [illegible] to 14 cc in

24 hours in divided doses digitalized most patients In practice one may inject 4 cc (0 8 mg) repeat in four hours and thereafter give 2 cc (0 4 mg) every six hours as indicated In cases of atrial fibrillation the ventricular rate sometimes falls to 40 or 50 within thirty minutes to two hours Maintenance doses of digitalis should be continued orally if possible after digitalization has been effected Digoxin gitalin[163] and digitoxin may also be given intravenously but have progressively longer latent periods than Cedilanid in the order named

Other commercial solutions of digitalis, provided in sterile ampules for intravenous injection are available for example digalen *digifoline or digitan According to Pardee* [80] a safe and satisfactory initial dosage is 6 to 8 cat units (0 45 to 0 60 mg) administered slowly If a satisfactory clinical result is not obtained within two or three hours a second injection of 2 cat units (0 15 gm) may be given and repeated again if necessary in three hours Slowing of the heart may occur within fifteen minutes but the maximum effect usually appears two to three hours after the injection and persists for 12 to 24 hours Digitalis should not be given intravenously if the patient has received digitalis in the preceding two weeks Often after the initial dose digitalis therapy can be continued orally in doses of 0 2 mg every six hours until the desired effect is obtained The above solutions have been administered in similar dosage intramuscularly or hypodermically when a vein cannot be entered and urgent digitalization is required

Rectal Administration of Digitalis

Digitalis may be administered rectally[21] to patients who cannot take oral medication because of nausea and vomiting due to congestive heart failure or to other causes but is now rarely used

EVIDENCES OF DIGITALIS OVERDOSAGE

Toxic manifestations are an essential feature of overdosage with any effective preparation of digitalis or of a drug with digitalis like action Claims that a given preparation of digitalis never produces such toxic symptoms are either untrue or indicate the inertness of the preparation concerned Patients differ greatly in their tolerance to digitalis consequently some present toxic symptoms with doses which are ordinarily considered inadequate therapeutically In some patients especially those with very severe congestive heart failure, the toxic and therapeutic doses are almost identical and it is difficult to obtain satisfactory clinical improvement without evoking mild and recurrent toxic symptoms

The occurrence of digitalis toxicity may be related to potassium metabolism Depletion of potassium sensitizes the myocardium to digitalis and induces toxicity with doses of digitalis which are ordinarily non toxic[218] Thus digitalis poisoning is likely to be induced in conditions associated with potassium loss due to vomiting, diarrhea, mercurial diuresis especially when mercurials are administered in association with ammonium chloride steroid therapy (cortisone or ACTH) or during treatment of diabetic ketosis with insulin and glucose These conditions are most apt to deplete the body of potassium when the dietary intake of potassium is diminished because of anorexia nausea or vomiting or other reasons Most often the body potassium depletion is not clearly reflected in the plasma potassium which remains within the normal range

Among other causes of digitalis toxicity besides unexplained grossly excessive dosage are the neglect of warnings of early poisoning and too vigorous exhibition of digitalis to the neglect of other measures in an effort to obtain a therapeutic effect Not infrequently digitalis toxicity occurs when there was no rational indication for the use of this drug[82]

The most common evidences of overdosage with digitalis are those representing (1) *gastrointestinal disturbances* and (2) *disturbances in cardiac rhythm*

Anorexia Nausea, Vomiting

Nausea and vomiting are the commonest early symptoms of digitalis overdosage Usually these are preceded for a day or two by moderate or complete anorexia When the latter is noted after an average therapeutic dose of digitalis the more annoying vomiting may be prevented by prompt discontinuance of the drug The vomiting is of central not of gastric origin for it appears even after intravenous injections of digitalis[170] and in animals nausea and vomiting movements were induced by Hatcher and Eggleston[169] following the administration of digitalis even when the gastrointestinal tract had been removed (However, local gastric irritation can result from large initial dosage of whole leaf tab

lets) Whether the vomiting results from direct stimulation of the vomiting center in the medulla or by a reflex from the heart is still a controversial question

The chief practical problem presented by the appearance of nausea and vomiting during the administration of digitalis is to determine whether these symptoms are due to the drug which would demand its discontinuance or to uncontrolled congestive heart failure (p 293) which would require continued or increased dosage Unfortunately for such decisions some patients as shown by Eggleston [89] vomit after only one half to two thirds of the usual digitalizing dose while others require as much as 8 o gm before vomiting appears If a beneficial therapeutic result has been obtained o if the dose administered is nearly equal to the amount estimated for digitalization it is best to discontinue the drug for one to three days and then resume it in smaller doses If less than two thirds of the estimated dose has been given when vomiting appears if there are no other toxic symptoms (such as bigeminal rhythm) and if the symptoms of congestive heart failure are still uncontrolled it is preferable to continue the digitalis despite nausea and vomiting with careful observation for the possible development of other toxic manifestations of the drug Nausea and vomiting in patients with congestive heart failure are often due not only to the congestive failure itself but also to other factors These symptoms frequently subside if food fluids and medication by mouth are eliminated for a brief period while sedatives are administered and digitalis is continued intravenously or rectally

Diarrhea was noted by Withering[356] as a consequence of digitalis but this is uncommon except with very excessive doses However when this symptom appears during digitalis medication the possibility that it represents intoxication with the drug must be considered Other evidences of digitalis overdosage will be found if this is the case

Cardiac Disturbances

Cardiac arrhythmias have occurred with increasing frequency since the use of the pure cardiac glycosides especially digitoxin This may be due to the recommended and widely accepted excessive maintenance dose of 0 2 mg of digitoxin daily but the slow cumulative action and delayed excretion of this drug may also contribute to its toxicity It is particularly noteworthy that the cardiac disturbances may be induced by digitalis toxicity without preceding or concomitant telltale gastrointestinal disturbances and even without the classic ST T effects of digitalis on the electrocardiogram

Premature Beats and Bigemini Next to the gastrointestinal symptoms premature beats (extrasystoles) are the commonest manifestations of digitalis overdosage A characteristic form of premature beats associated with digitalis overdosage is that termed *bigemini* an arrhythmia in which every normal beat is followed by a premature contraction (Fig 57) Various premature beats including bigemini also occur in patients who have not received digitalis When such patients are in heart failure digitalis is not contraindicated and the medicament may actually eliminate the premature beats When however bigemini first appear during full digitalization they must be interpreted as an evidence of overdosage and the digitalis should be interrupted for at least a day after they disappear If the premature beats (isolated or in bigeminal rhythm) are due to digitalis they are almost always of ventricular type and vary in electrocardiographic configuration because they are of multifocal origin [33] Sometimes alternating left and right ventricular premature beats are seen with

Fig 57 Digitalis intoxication Bigemini due to regularly recurrent ventricular premature beats

toxic doses of digitalis In patients with atrial fibrillation, the presence of bigemini may still be recognizable by the coupling of the pulse produced during the periods of extrasystoles but often electrocardiograms are necessary for their discovery in such cases Electrocardiographic observation is essential powdered leaf Usually, however they appear after an adequate therapeutic dosage

Disturbances in Conduction *Excessive slowing of the pulse* is another evidence of digitalis overdosage Usually the drug should be discontinued if the heart rate falls below 60 per min and almost always if it falls below 50

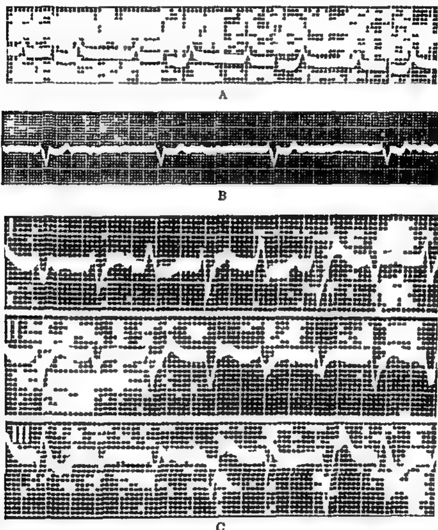

Fig 58 Digitalis intoxication

B Atrioventricular dissociation Idioventricular pacemaker with regular rhythm despite atrial fibrillation Complete heart block Lead II

C Ventricular tachycardia of multifocal origin

to discover toxic cardiac disturbances when ever digitalization is being effected when digitalis dosage is being changed, and from time to time as the maintenance dose is established While extrasystoles in animals occur only after huge doses (50 to 75 per cent of the lethal dose) in man they may appear after only three or four doses of 0 1 gm of the

Various grades of partial *heart block* or complete heart block occur (Fig 58) McGuire and Richards [33] reported the development of complete heart block in the normal heart of a person who took 30 gm of digitalis with suicidal intent In a series of 71 cases of complete heart block studied by Ide [111] digitalis was responsible in 12 In patients

with congestive heart failure digitalis often causes partial heart block due to impairment of atrioventricular conduction But this may occur occasionally even with therapeutic doses If such dosage is not exceeded digitalis may be administered to patients who already show partial heart block without increasing the delay in conduction

Disturbances in Sinus Rhythm and Sinoatrial Conduction By its vagal action toxic doses of digitalis may depress sinoatrial impulse formation or sinoatrial conduction As a result digitalis may induce sinus arrhythmia sinus arrest [111] sinoatrial block [16] and atrial standstill By a similar mechanism of sinus depression digitalis intoxication may evoke atrioventricular nodal rhythm nodal tachycardia [311] nodal rhythm with atrioventricular dissociation and interference beats (Fig 59) These arrhythmias are discussed in Chapters 13 14 and 15

Fig 59 Interference dissociation due to digitalis intoxication Ventricular rate 120 atrial rate 115 per minute Third and tenth ventricular complexes (interference beats) are responses to conducted sinus impulses

Atrial Fibrillation and Tachycardias *Atrial fibrillation* is frequently induced by therapeutic doses of digitalis in patients with atrial flutter (p 357) However this and rarely *atrial flutter*[111, 43] *may develop in* hearts with normal rhythm after toxic doses of digitalis [271, 43] *Tachycardia* as well as ex*cessive slowing of the heart may represent* digitalis intoxication This may be due to numerous ventricular extrasystoles which result *from excessive digitalis (Fig 58C) If* the toxic significance of the tachycardia is unrecognized and digitalis therapy continued *paroxysmal ventricular tachycardia* may result [131] Ventricular fibrillation may be a possible consequence of overdigitalization[108] *and may account for cases of sudden death* due to intravenous strophanthin Enselberg and associates[109] and Burrell and Coggins[51] *reported cases of ventricular fibrillation fol*lowing the intravenous administration of acetylstrophanthidin In humans who were *subject to attacks of ventricular fibrillation* Schwartz and Jezer[285] were able to precipitate *such paroxysms with digitalis*

Other arrhythmias have also been occasionally evoked by toxic doses of digitalis *These include electrical and pulsus alternans* and paroxysmal atrial tachycardia with or without [illegible] block [177] The latter was induced repeatedly even with small doses of digitalis In the past few years the occurrence of paroxysmal atrial tachycardia with block as a manifestation of digitalis toxicity has been reemphasized [17, 16] It may be mistaken for atrial fibrillation or impure flutter and erroneously lead to increased digitalis dosage When this arrhythmia occurs in patients with heart failure treated with digitalis it often appears to be related to potassium depletion and its elimination may be hastened by the administration of potassium as well as by discontinuing digitalis *A rapid* ventricular rate associated with atrial fibrillation and overdigitalization may be slowed by the administration *of potassium (Fig 60)*

Treatment of Toxic Arrhythmias due to Digitalis or Strophanthus. Digitalis is discontinued until several days *after all signs of toxicity are* abolished Therapy of digitalis induced arrhythmias has been advanced by the use of *procaine amide (Pronestyl) (p 350) and by* the administration of potassium salts (p 341) The benefit of potassium salts in the *control of ectopic cardiac rhythms has long* been known [61] Now it has been found especially valuable to reduce myocardial irri*tability specifically* due to digitalis by restoring myocardial potassium depleted by digitalis [281, 111, 311] Sampson and associates[234] eliminated digitalis induced extrasystoles with 5 to 10 gm of potassium acetate in a 25 per cent solution The response was usually obtained in 40 minutes and persisted three to eight hours In addition to the specific use of potassium Pronestyl quinidine and other agents may be used to control the various

types of cardiac arrhythmias due to digitalis, just as they would be employed in the therapy of the same arrhythmias due to other causes Magnesium has been found effective in abolishing extrasystoles bigemini and ventricular tachycardia caused by digitalis [2] Many of

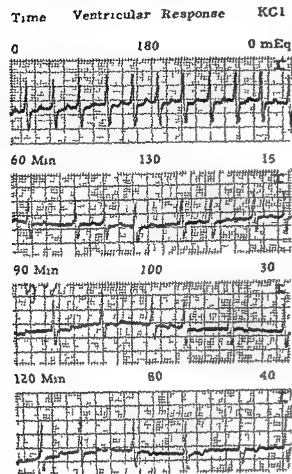

Fig 60 Atrial fibrillation associated with digitalis toxicity treated with potassium Following maintenance on 0 3 gm of digitalis leaf daily for three months patient experienced a paradoxical increase in ventricular rate with regularization of R R interval after a profuse mercurial diuresis (with loss of potassium) Ventricular rate slowed progressively within two hours after intravenous administration of 40 milliequivalents of potassium chloride in 5 per cent glucose in distilled water (Courtesy Dr Marvin Bachner)

the arrhythmias induced by digitalis and many of the other manifestations of digitalis toxicity resemble similar disturbances due to the underlying cardiac disease or heart failure and the problem arises whether to discontinue digitalis or whether the findings actually denote that the patient has not been adequately digitalized. Sometimes a careful history reveals that the manifestations which might be attributed to digitalis were present before digitalis was begun, or at a time when the dose of digitalis was too small to be considered causal On the other hand, if there is any doubt it is preferable to discontinue digitalis for a few days or longer if the symptoms appear to improve or not to worsen At the same time all other measures for treating heart failure are utilized But if it becomes apparent that the symptoms were not due to digitalis digitalization can be effected rapidly

Nervous and Other Symptoms

Headache is relatively common with excessive digitalization Occasionally visual blurring scotomata or colored vision (green and yellow) is produced [276] Weakness and mental disturbances are not uncommon especially in elderly patients Despite the criteria set down by Carr[35] for attributing mental or psychotic disturbances to digitalis overdosage, it is often difficult to distinguish such a relationship for the symptoms in cases which I have observed could also be attributed to rapid or excessive dehydration caused by restriction of fluid and salts, and especially to the diuresis produced by mercurial salts [341] I have observed similar symptoms following excessive diuresis in patients with heart failure who have received no digitalis Batterman and Gutner[17] described unusual neurologic manifestations of digitalis toxicity in 10 patients, characterized particularly by neuralgia of the lower third of the face mandible or maxilla and by pain in the upper extremities lower lumbar and calf muscles Mental symptoms may also be due to advanced heart failure per se or to associated renal insufficiency

Other Toxic Effects

Eosinophilia attributed to marked vagotonia caused by digitalis, has been noted by several observers [77, 178] Allergic disturbances such as urticaria[358] have been described [88] Dangerous and sometimes fatal results have been reported as resulting from the combined or successive administration of digitalis and other drugs especially ephedrine[188] and calcium [307] When dealing with patients with heart failure however one must be cautious in attributing sudden death to an extraneous factor

Increasing Cardiac Failure or Intractable Heart Failure

Overdigitalization sometimes appears to be responsible for increasing cardiac failure or

for heart failure becoming intractable and refractory to treatment. Whether this represents some direct toxic effect on the myocardium or whether the effect is due to electrolyte disturbance (potassium depletion) is uncertain. There is evidence that digitalis and ouabain drive potassium out of the heart muscle cells and possibly deplete their energy rich phosphates.[254] In practice one should investigate the possibility of overdigitalization in every patient with intractable heart failure.

Thrombotic Effect of Digitalis

There have been claims that digitalis increases the coagulability of the blood, but this has been disputed.[11] The importance of this question lies in the purported tendency of digitalis to promote fatal embolization. This danger has been particularly emphasized in cases of acute myocardial infarction in which digitalis has been employed.

Pathologic Myocardial Lesions

After large toxic doses of digitalis given to animals, microscopic examination reveals areas of focal necrosis, vacuolization or dissoluton of muscle fibers, hemorrhages, cellular infiltration and fibrosis.[19] Kyser and his associates[202] called attention to the similarity of these anatomic abnormalities to those caused in dogs by vagal stimulation or injections of acetylcholine. These similarities and their own experimental observations led them to conclude that the cardiotoxic effect of digitalis in the dog is due to vagal stimulation which causes coronary vasoconstriction. Atropinization or drugs causing coronary vasodilatation (aminophylline, theobromine) diminished the lesions produced by digitalis. Digitalis induced myocardial lesions have been reported in the presence of experimental hyperthyroidism in cats.[84]

THE EFFECT OF DIGITALIS ON THE ELECTROCARDIOGRAM

It is extremely important to be familiar with the electrocardiographic changes caused by digitalis because some are characteristic of the drug and others may be indistinguishable from the changes caused by myocardial disease, especially that due to coronary arteriosclerosis and occlusion. Digitalis has been employed by persons with normal hearts in order to mislead their physicians into making a diagnosis of myocardial disease with the aim of illicitly collecting disability insurance. The electrocardiogram is useful in discovering or confirming the presence of cardiac changes due to digitalis overdosage.

The earliest and most important electrocardiographic effects of digitalis are on the RS-T interval and T wave (Fig. 58-1). These occur in persons with normal as well as diseased hearts. They occur before full therapeutic benefits are obtained and therefore are no indication for discontinuing the digitalis.

A depression of the RS-T interval followed by an inversion of the T waves is the characteristic change of digitalis[64, 114, 111] (Fig. 58A). Shortening of the Q-T interval and lowering of the T wave[111] are also early effects of digitalis. The exact changes encountered differ somewhat in normal hearts and in those which showed electrocardiographic alterations before digitalis was begun. In *normal hearts* the chief effect is on the RS-T interval, the changes in the T wave being secondary to the displacement of the origin of the RS-T interval. The ST level first becomes depressed so that it begins below the isoelectric line and forms a curve which is concave upward. Later the S-T interval, starting below the isoelectric line, turns sharply downward and then forms a right angle as it turns up again to join the T wave. Finally the upward (second) limb of the ST segment turns up more sharply so as to form an acute angle. There is no true inversion of the T wave since its peak is still above the isoelectric line, but the changes in the S-T interval make the T wave appear either inverted or diphasic. Another characteristic is the slow downward slope from the peak of the T wave so that it hardly reaches the baseline when it joins the next P wave. These changes in the S-T interval and T wave are characteristic of digitalis and should not be mistaken for the T waves caused by myocardial disease.

In *diseased hearts* whose T waves were originally upright, the ST changes with digitalis are often indistinguishable from those in normal hearts. Frequently, however, digitalis produces alterations in such hearts which are indistinguishable from those due to myocardial damage secondary to coronary artery disease. There is a distinct ST segment depression which may be convex upward and a pronounced inversion of the T wave.

If, however, the T waves are inverted in all leads before digitalization, they usually become less inverted after digitalization, or the

S-T interval may become depressed without significant change in the T waves On the other hand if there is only slight inversion of the T waves before digitalis the drug may increase the negativity of these waves Occasionally negative T waves are rendered upright by digitalis In cases with left axis deviation with upright T waves the S T interval in lead I may become depressed and T_1 inverted while ST_3 becomes elevated and T_3 upright thus resembling the changes seen in anterior myocardial infarction

In the precordial leads Strauss and Katz[3 9] observed a depression or elevation of the S T interval and diminution in the size of the T wave Rarely the T wave disappeared or became inverted RS T segment deviations and T wave abnormalities in the precordial leads may simulate those due to coronary occlusion with myocardial infarction[319] Beers et al[16] found the most striking digitalis changes in the left precordial leads when the electrocardiogram disclosed a transverse electrical axis and in the right precordial leads when the electrical axis was vertical

Certain diagnostic conclusions can be drawn from the ST and T changes in the electrocardiograms of patients receiving digitalis If they are the changes mentioned as being characteristic of digitalis the patient may have a normal or a diseased heart But if distinctly inverted T waves appear during digitalization it is extremely likely that the heart is diseased for the normal heart develops only the ST changes described as characteristic of digitalis Since the ST and T changes which may appear within two to four hours of a large therapeutic dose do not disappear for two to three weeks it is necessary for proper interpretation of the electrocardiogram to determine whether the patient has received digitalis in the preceding three weeks It has been noted (p 51) that repolarization occurs last in the subendocardial myocardium despite the fact that depolarization appears earlier here than in the subpericardial muscle This delayed repolarization accounts for the ventricular gradient which as a rule renders the normal T wave upright otherwise it would be inverted (opposite in direction to the QRS) Digitalis appears to accelerate the repolarization in the subendocardial region reduces or eliminates the differences in duration of repolarization in the myocardium and thereby abolishes or greatly reduces the ventricular gradient The ST-T waves of repolarization become oppositely directed to the QRS and usually negative[345] At the same time this accelerated repolarization shortens electrical systole[346] (QT_c)

Other electrocardiographic changes appear later and usually only after excessive doses of digitalis They are the graphic representation of the disturbances in rhythm and conduction enumerated above as the cardiac symptoms of digitalis overdosage (p 265) These include premature beats especially bigemini excessive slowing of the heart rate prolongation of the P R interval (Fig 58*A*), partial or complete heart block with dropped ventricular beats or atrioventricular dissociation (Fig 58*B*) atrial fibrillation ventricular paroxysmal tachycardia (Fig 58*C*) and inversion flattening or notching of the P wave especially in lead III The P wave changes can usually be eliminated by atropine The duration of electrical systole i e the Q T interval is shortened in comparison with the duration of the entire cardiac cycle R R[20] According to ter Horst[3 8] the *absolute* value of the Q T interval may be shortened lengthened or remain unchanged depending on whether it was originally prolonged of normal length or of less than normal length

DIURETICS

In cases of relatively mild congestive heart failure rest and limitation of salt often result in a satisfactory diuresis with concomitant clinical improvement In others, such an effect is obtained only if digitalis therapy is also employed But many patients with more severe symptoms of congestive heart failure especially with widespread anasarca, respond satisfactorily only if diuretics are utilized in addition to the above measures The fewer the measures required to obtain a good therapeutic result the better in general is the prognosis A variety of diuretics have had their vogue from time to time but the utility of any one of these has been dwarfed by the striking success of the soluble organic mercury salts Since the mercurial diuretics have been used many patients whose outlook for life would not average more than six months to a year have been maintained with various degrees of comfort for many years

MERCURIAL DIURETICS

Mercuhydrin and Other Mercurial Diuretics *Calomel* formerly widely employed as a diuretic often in combination with equal parts of digitalis and squill (1 gram each) as the famous Guy s pill is now rarely used in treating cardiac dropsy because of its limited effectiveness and its toxicity *Merbaphen* (Novasurol), originally used in the treatment of syphilis is an effective diuretic but is rarely used at present because of toxic complications Colitis stomatitis purpura hemoglobinuria hemorrhagic encephalitis and epithelial necrosis of the kidney sometimes with fatal results have been reported These complications are relatively rare with the more recently employed mercurials *Salyrgan* (mersalyl) *mercupurin* or *Mercuzanthin* (mercurophylline) *Mercuhydrin* (meralluride sodium) *Thiomerin* (mercaptomerin sodium) and *Cumertilin* (mercumatilin) The mercurial diuretics now in use usually contain about 5 per cent of theophylline which may add somewhat to the diuretic effect facilitates absorption of the mercurial component and probably reduces local irritation [88]

Thiomerin is one of the newer mercurials with a mercapto or thiol (SH) group in the mercurial molecule obtained by adding thioglycollate instead of theophylline to reduce toxicity Aside from a reported diminution in cardiotoxicity of Thiomerin in animals as compared with other mercurials Thiomerin was found to produce less local irritation and was considered to be suitable for subcutaneous injection Although many observers have reported the use of Thiomerin by subcutaneous injection with relatively few and infrequently severe local reactions [14] Gold and associates[144] reported disturbing local reactions in about 25 per cent of the patients and noted no significant advantage over Mercuhydrin for subcutaneous administration One disadvantage of Thiomerin is its lesser stability than other mercurials when placed in solution

Dicurin procaine (merethoxylline procaine with theophylline) is a new organic mercurial each cubic centimeter containing 0 1 gm of merethoxylline as the procaine salt (equivalent to about 40 mg of mercury) with 5 per cent theophylline added Although Dicurin procaine was recommended to be useful for subcutaneous injection because of minimal local reactions Best et al [27] reported that local reactions including ecchymoses were observed in 20 per cent of patients and following 8 per cent of the injections

Cumertilin (*mercumatilin*) is still another new mercurial diuretic which differs structurally from other mercurial diuretics in that the mercurated methoxypropyl group has no amide linkage and is attached to a ring carbon atom, the ring structure in this compound is a heterocyclic coumarin Like the other currently available mercurials it is prepared in a solution for injection each cubic centimeter containing a concentration of 30 mg mercury and 50 mg of theophylline It is also prepared in tablets for oral administration [285] Preliminary studies indicated Cumertilin is as potent as other mercurial diuretics by injection[279] [4] and that its toxicity and local effect on tissues are likewise similar [24] In a limited experience I have encountered relatively more local painful reactions than with either Mercuhydrin or Thiomerin Data were presented indicating that ammonium chloride is not as essential for a satisfactory diuresis with mercumatilin as with meralluride or other mercurial diuretics [4]

At the present time I most frequently employ Mercuhydrin but have found Thiomerin equally satisfactory except for its lesser stability From the viewpoint of activity Salyrgan Mercuhydrin and Thiomerin have been found equally potent [110] [148] and Citrin and Lyons[80] reported Dicurin procaine to be as potent as Thiomerin

Action of Mercurial Diuretics

The mechanism by which the mercurial salts produce diuresis is uncertain According to the studies of Herrmann and his coworkers [174] the mercurials cause diuresis by liberating ionic mercury which inhibits tubular reabsorption Sollmann and associates[308] found evidence to indicate that they may have an extrarenal action by which they mobilize water and salt from the tissues into the blood stream However the extrarenal theory of mercurial diuresis has been generally rejected on the basis of considerable experimental evidence [158] [7] It is most probable that the mercurial diuretics act directly on the kidneys [158] [7] decreasing the tubular reabsorption of chloride sodium and water [244] In addition they inhibit tubular reabsorption and secretion of potassium [58] [81] There is no significant change in renal blood flow or glomer

ular filtration The striking increase in volume of urinary output after a mercurial diuretic, especially in the patient with heart failure is not due to direct effect on water flow by primary inhibition of tubular reabsorption of water[5] Rather the primary inhibition of chloride and sodium ions secondarily interferes with the passive reabsorption of water in the proximal or distal tubules or the depression of tubular reabsorption of these ions may *increase the urinary load of solutes and* thus impose an osmotic limitation on active tubular reabsorption of water There is evidence that the mercurial diuretics inhibit specifically the reabsorption of chloride ions[236] and that the cations sodium and potassium are carried along with the unresorbed chloride Whereas the concentration of sodium in plasma and therefore in the glomerular filtrate exceeds that of chloride (140 compared with 105 mEq per liter respectively) following a mercurial diuretic the urinary concentration of chloride usually equals or exceeds that of sodium[1,3, 5] However mercurial drugs may have a direct inhibitory effect on tubular reabsorption of sodium as well as chloride[■]

There is a difference of opinion as to whether the site of action of mercurial drugs ■ the proximal or the distal tubule and there is uncertainty as to the mechanism by which tubular inhibition of ionic reabsorption is accomplished The experimental observations of Weston et al [249] Mudge et al [250] and others[273, 43, 243, 180] were interpreted to indicate that mercurials acted on the proximal tubule and this viewpoint appears to be supported by *the finding that in mercurial anuria the* pathologic lesions are essentially in the proximal tubule ■ On the other hand, the ingenious experiments of Duggan and Pitts[95] suggested to them that the mercurial acted on the distal tubule For the fraction of total sodium reabsorption blocked by mercurial action (17 to 21%) coincided closely with the fraction of sodium filtered through the glomerulus which is not reabsorbed by the proximal tubules and is available for distal tubular reabsorption *The theory of distal* tubular action of mercurial is al o supported by the studies of Dale and Sanderson [75] and by the observations that these drugs depress the maximum tubular excretory capacity for Diodrast and PAH [43] which are functions of the distal tubules

More recently histochemical studies likewise suggest ■ distal tubular site of action of mercurial diuretics and also support our present concept of the manner of action of organic mercurial diuretics on tubular function The interference of mercurials with tubular reabsorption of certain ions and water, their depression of tubular excretion of dyes and their inhibition of potassium secretion[21] indicate that the mercurials exert ■ toxic effect on the tubules *which interferes with* fundamental functions The transient and reversible nature of this effect ■ compatible with enzyme inhibition Succinic dehydrogenase an enzyme important in the citric acid (Krebs) cycle, and depending for its activity on the presence of free sulfhydryl (SH) groups, ■ believed to play an important part in the chemical reactions whereby the tubule cells provide the energy necessary for osmotic work required for the active absorption of ions Mercuric salts including mercurial diuretics are capable of inactivating succinic dehydrogenase [161, 8 8] On the other hand BAL which reverses the toxic effects of the poison gas lewisite (an inhibitor of SH enzymes), does so by providing SH groups which compete with the SH enzyme and thus inactivate the lewisite BAL similarly reverses the mercurial inhibition of succinic dehydrogenase[8, 161] and simultaneously diminishes or arrests mercurial diuresis [116] These observations suggest that succinic dehydrogenase is important for tubular reabsorption and that mercurial diuretics inhibit tubular reabsorption of chloride sodium, etc, by combining with the free sulfhydryl groups and thus inhibiting or *inactivating the enzyme succinic dehydrogen*ase [83] In order to localize the site of this inhibition, the blue stain tetrazolium was used as an indicator, acting as a hydrogen acceptor for succinic dehydrogenase and combining with it to form dark blue crystals of formazan, which may be observed microscopically By this method it was noted that succinic dehydrogenase activity ■ greatest in the cells of Henle s loop but more striking was the finding that after administration of a mercurial *diuretic, formazan crystal formation* denoting succinic dehydrogenase activity was minimal or absent in the thick (distal ascending) limb of Henle s loop [251] These findings were interpreted to indicate that mercurial diuretics act on the distal tubules

The pronounced diminution of sodium ex

cretion by the kidney which is characteristic of congestive heart failure ■ reversed by mercurial diuretics Following intravenous injection diuresis begins within one to two hours after administration of the mercurial reaches its peak in four hours and is usually completed in twelve to twenty four hours A daily excretion of 2 to 3 liters is commonplace after a mercurial diuretic and concomitantly there is a weight loss of 3 to 6 pounds Occasionally huge amounts of urine are excreted Careful attention to the weight ■ a useful method of gauging the effectiveness of the diuretic

Indications for Mercurial Diuretics

The mercurial diuretics are indicated in all stages of congestive heart failure but especially when the symptoms fail to respond to rest digitalis and the limitation of sodium salts The most striking benefits are seen in patients with intense anasarca but a sharp diuresis and loss of weight are frequently observed in patients with latent edema Furthermore remarkable benefit may be obtained from the mercurial diuretics in cases of congestive heart failure (pulmonary congestion with or without pulmonary edema) in which failure is limited to the left side of the heart Patients with orthopnea nocturnal dyspnea (cardiac asthma) nocturnal cough due to heart failure or with recurrent attacks of pulmonary edema may be greatly relieved by the administration of the organic mercurials Mercurial dehydration may be indicated as a prophylactic measure against recurrent paroxysmal dyspnea In such patients the administration of mercurial diuretics often serves as a therapeutic test in determining the cardiac or noncardiac origin of protracted cough or dyspnea of uncertain origin

The mercurial diuretics are equally effective in cases of congestive heart failure with atrial fibrillation or with regular rhythm But compared to digitalis effects their action is much more impressive in the latter group in which digitalis often fails to produce a significant diuresis Frequently the mercurial diuretic will evoke a sharp diuresis and loss of edema after rest and digitalization have been given a fair trial without much benefit Cases of congestive heart failure due to coronary atherosclerosis hypertension or rheumatic heart disease respond to the mercurial diuretics with equal effectiveness

Contraindications to Mercurial Diuretics

The chief contraindication to mercurial diuretics is renal impairment But albuminuria or nitrogen retention in the blood does not necessarily forbid the use of these drugs because heart failure itself may produce these abnormalities That they are actually due to heart failure and not to renal insufficiency may be recognized by the dark color of the urine with its richly colored sediment and by the high specific gravity of the urine (1 020 or more) as obtained in a casual specimen or after a concentration test On the other hand if the urine is pale and the specific gravity is 1 014 or less in patients with heart failure it is probable that there is renal insufficiency and mercurials should not be administered This rule is not applicable if the urine is examined when the patient is in the process of active diuresis But although the administration of a mercurial diuretic may be permissible in a patient with heart failure complicated by renal disease further injections are contraindicated if a satisfactory diuretic response is not obtained And indeed in all patients with severe heart failure lack of a significant diuretic effect is a warning against further mercurial diuretics unless some interfering factor ■ altered or adjuvant drugs are used

The mercurial diuretics are contraindicated when heart failure is associated with acute or subacute glomerulonephritis as they may increase the hematuria or cause anuria I have seen both temporary and fatal anuria caused in such cases by the use of Salyrgan or mercupurin However further study of the possible usefulness of mercurial diuretics in renal edema is needed One of the major risks of the use of mercurial diuretics in glomerulonephritis is the danger of mercurial retention if a diuresis is not obtained and especially if there is severe oliguria However mercurial drugs frequently produce an excellent diuresis in patients with chronic glomerulonephritis with edema The mercurial diuretics should be used with caution and in relatively small doses in elderly patients who are likely to have urologic diseases Tscherning[318] has reported the occurrence of acute retention in old men with large prostate glands which was attributed to a profuse Salyrgan diuresis I have observed this many times Hines[161] reported a high incidence of uremia in a series of

patients with hypertensive and coronary heart disease and congestive heart failure

Mercurial diuretics irritate the colon and are therefore contraindicated in the presence of *inflammatory lesions of the large bowel* For the same reason it is advisable not to administer purgatives acting on the colon on days when Salyrgan or mercupurin is administered The mercurial diuretics are contraindicated in persons with a hypersensitivity to the mercury ion and Dicurin procaine should not be given to persons sensitive to procaine

Toxic and Other Undesirable Effects of Mercurial Diuretics

The toxic and undesirable effects of mercurial diuretics may be considered under five headings

1 Immediate reactions
2 Mercurialism
3 Local irritation
4 Digitalis toxicity
5 Electrolyte disturbances

1 Immediate Reactions A number of serious and even fatal reactions have been reported immediately after injection of mercurial diuretics, even in patients who had had many previous injections of the same drug[351] These are rare with the first injection and when mild reactions occur subsequently they tend to become more severe with repeated administration Chills, fever[339] nausea and vomiting and cutaneous rash, occurring on the day of injection have been attributed to drug idiosyncrasy Sometimes these are warning reactions more severe manifestations occurring with continued exhibition of the mercurials[46] Among the immediate reactions to the injection of mercurial diuretics are transient dizziness, weakness pallor, perspiration substernal oppression, dyspnea or asthmatic attacks and changes in cardiac rhythm They occur very rarely In some instances collapse and sudden death have followed an injection of a mercurial diuretic[45] The cause of these reactions is uncertain[351] Ben Asher[18] believed that he prevented a recurrence of reaction by injecting the mercurial very slowly or giving it after an intravenous infusion of sodium thiosulfate or by injecting it intramuscularly Sometimes a change to another mercurial eliminates further untoward reactions In these circumstances sensitivity is not related to the mercury ion but to the given organic compound

2 Mercurialism Manifestations of mercurial poisoning are relatively rare with the organic mercurial preparations now in use Safety is provided by the excretion of 70 to 85 per cent of the mercurial in 24 hours if there is a diuresis of at least 2000 cc[194] Stomatitis with excessive salivation, dermatitis, colitis with diarrhea which may be hemorrhagic, and renal disturbances (hematuria, anuria and renal insufficiency) have been reported on occasion If mercurial toxicity is recognized early treatment with BAL should be instituted (initial dose 5 mg / kg) or about 3 cc of a 10 per cent solution of BAL in benzyl benzoate and peanut oil intramuscularly followed by 1 5 to 2 5 mg /kg (usually 1–1 5 cc) every four hours thereafter for at least three days

3 Local irritation is an annoying characteristic of the mercurial diuretics Imperfect intravenous injections cause a severe periphlebitis with pain and disability lasting several days, and occasionally followed by tissue necrosis, but such local tissue reactions are much less common with mercuhydrin and Thiomerin than with Salyrgan theophyllin or Mercuzanthin It is essential that the needle be properly placed within a vein before the drug is injected and repeated aspiration of blood should be performed to be certain the needle has not slipped

4 Digitalis Toxicity and Redigitalization Another reported complication of rapid diuresis with mercurials is the mobilization of digitalis from edema fluid and serous effusions[90] It was reported that some of the digitalis is retained in the edema fluid[4] In the course of active diuresis the digitalis containing extracellular fluid has been presumed to reenter the bloodstream and to cause redigitalization or excessive digitalization of the patient with consequent ventricular slowing arrhythmias vomiting and mental confusion This theory is improbable because quantitative studies disclosed minimal or no digitalis in the edema fluid of digitalized patients[315] It is highly probable that mercurial diuresis predisposes to and precipitates digitalis toxicity by depleting body potassium A direct myocardial toxic effect has been predicated to account for cardiac arrhythmias induced following mercurial diuresis But the "myocardial effect may represent potassium depletion

According to Macht[274] injection of mer

curial diuretics reduced the clotting time of the blood of rabbits and cats Marvel and Shullenberger [8] reported thromboembolic phenomena associated with rapid diuresis in the treatment of congestive heart failure They recommended the use of prophylactic anticoagulant therapy

Despite the occasional toxic effects of mercurial diuretics these drugs are rarely dangerous if used with discretion and with regard to the above contraindications There are many patients now who have received many hundreds of injections of mercurial diuretic without apparent harm Fineberg[124] has reported a case in which 343 injections of Salyrgan and mercupurin were given without deleterious effect over a period of seven and one half years Friedenson[135] reported a similar case in which 627 injections were administered over a period of twelve years I have given one patient with heart failure due to rheumatic heart disease more than 700 intravenous injections of mercurial diuretics, and many others have received approximately one injection weekly for more than five years Tarr and Jacobson[3,6] in a study of 30 necropsies on subjects who had received Salyrgan for a long time found indications of renal damage caused by the mercurial in only one case

5 Disturbances in Blood Electrolyte Pattern

Effects of Excessive Mercurial Diuresis Enthusiasm for the mercurial diuretics especially in combination with low sodium diets was soon followed by observations of unpleasant and sometimes serious clinical manifestations attributed to excessive and too rapid diuresis Muscular fatigue muscle cramps weakness and occasional prostration or collapse were attributed to dehydration and especially to loss of electrolytes particularly sodium Psychotic disturbances (drowsiness, mental confusion delirium) often attributed to digitalis toxicity, may also be due to overenthusiastic use of the mercurials Some of the cases of so called cardiac cachexia may be due in part at least to mercurial diuretics Poll and Stern [64] reported seven such cases with three deaths due to rigid mercurial diuresis After a period of preliminary weakness intense anorexia and mental apathy the patients suffered from restlessness, mental confusion and rarely hallucinations and delirium Progressive coma and death ensued in some cases Following vigorous desalting with mercurials fixation of the specific gravity of the urine at 1 010 and azotemia may persist for several weeks Black and Litchfield reported eight cases of uremia five of them fatal among 62 patients with heart failure treated with low salt intake and mercurial diuretics [2] Cerebral thrombosis with hemiplegia has been attributed to profound diuresis and the fall in blood pressure engendered by the injection of mercurial diuretics in full therapeutic doses [2,3] Occasionally profuse diuresis was held accountable for a loss of calcium sufficient to produce tetany in predisposed individuals [6] Other metabolic disturbances associated with intense diuresis have been postulated to account for the instances in which an attack of gout was precipitated in gouty persons [248]

In recent years distinctive disturbances in blood electrolyte pattern have been recognized in patients in heart failure who are being treated with mercurial diuretics alone or in combination with adjuvant diuretics low sodium diets and by cationic resins (Fig 61) Clinical syndromes characterized by many of the features listed above and others have been attributed to these chemical disturbances involving electrolytes and other blood constituents These will be individually considered

Hyponatremia the Low Sodium Syndrome [29, 210, 61, 224, 208] In certain patients with congestive heart failure the blood electrolyte pattern is characterized by a striking reduction in the concentration of plasma sodium (hyponatremia) to levels of 130 to 110 mEq /L or occasionally lower Correspondingly there is a diminished concentration of anions involving both chloride and bicarbonate There is a mild to moderate acidosis and often variable azotemia These chemical changes have been associated with a clinical picture which has been variously termed the salt depletion syndrome or ' the low sodium syndrome ' The implication is that depletion of the body salt or the low plasma sodium concentration and associated electrolyte disturbance are responsible for the clinical syndrome

Mechanism and Types of Hyponatremia There is considerable confusion in clinical practice with respect to the mechanism responsible for the clinical picture and electrolyte disturbance and with respect to the rela

tionship of the clinical picture to the blood electrolyte disturbance A low sodium concentration in the plasma (below 130 mEq/L) is seen in conditions with malnutrition such as chronic tuberculosis and in a variety of other chronic conditions, without any clinical manifestations of the so-called low sodium syndrome and in fact without any symptoms at all due to the low sodium[8,9] The hypo-osmolarity in this chronic asymptomatic form of hyponatremia may be due to nutritional disturbances affecting primarily cellular electrolyte concentration The plasma (and extracellular) low sodium concentration may represent a secondary adjustment whereby sodium metabolism is regulated around this new low level The total store of extracellular sodium as well as extracellular sodium concentration, is low[77] This group of cases is significant in two respects First it indicates that clinical manifestations do not necessarily result from hyponatremia Second in at least some cases of heart failure, chronic malnutrition may be entirely or partly responsible for hyponatremia and none of the clinical manifestations can be properly attributed to this chemical change

In a second group of cases the low sodium electrolyte pattern can be truly attributed to *sodium depletion* Sodium depletion is observed in surgical patients whose sole intake consists of parenteral fluid containing no sodium, in patients with fistulas or drains causing large daily losses of intestinal, biliary or pancreatic fluids, in patients with severe protracted vomiting or diarrhea without concomitant sodium replacement, in Addison's disease and sodium losing nephritis, and in subjects with intense sweating in a hot environment Sodium depletion occurs in congestive heart failure when there is a combination of low sodium intake with excessive sodium loss Low sodium intake may be due to anorexia or extremely restricted sodium intake, the increased output may be due to profuse diuresis induced by mercurial diuretics to paracentesis of ascitic fluid to thoracentesis, to diarrhea and to excessive

ELECTROLYTE PATTERNS CONGESTIVE HEART FAILURE

sweating in hot weather. The onset of the clinical and chemical features of sodium depletion may occur rather acutely after the diuresis or after the pleural or abdominal tap.[144] In this group dilution occurs due to greater loss of sodium than of water, but external loss of sodium is the primary factor.

In a third group of cases, often erroneously included under the category of sodium depletion, a sharply reduced sodium intake is an important causative factor but there is no evidence of abnormal sodium loss. Whatever the contributory role of mercurial diuretics, they do not act by causing a profuse diuresis and sodium depletion. On the contrary, the mercurials may be ineffective in producing diuresis and commonly there is oliguria; the sodium concentration of the urine is extremely low or sodium may be virtually absent. At the same time that the sodium intake is extremely low, the intake of fluids is unrestricted and there may be a positive water balance in view of the common oliguria. Thus the hyponatremia in these cases without sodium depletion is attributed to *water dilution of the extracellular sodium*. It is possible that a shift of extracellular sodium into bone or cells[24] also contributes to the hyponatremia. Occasionally *dilution hyponatremia* may be acutely complicated by sodium depletion due to isolated or repeated thoracentesis or abdominal paracentesis. In this type of dilution hyponatremia, associated with severe cardiac or renal insufficiency or cirrhosis of the liver, the total store of extracellular sodium is increased despite the low sodium concentration.

The mechanism of the dilution type of hyponatremia is obscure because the dilution explanation does not provide the reason for its occurrence in some patients with congestive heart failure but not in others receiving essentially the same dietary intake of sodium and similar diuretic therapy. Although there is no general agreement on this point, underlying renal impairment appears to be a common and important, if not essential, underlying factor responsible for the development of the dilution type of hyponatremia.[illegible] It is not clear whether the low sodium intake and the mercurial diuretics in combination cause further renal damage to a predisposed kidney and thereby then induce hyponatremia, or whether the kidney function is already sufficiently impaired and the low sodium mercurial combination merely prevents restoration of isotonicity of extracellular fluids by sodium while water is being retained by the malfunctioning kidney. It is of interest that the dilution type of hyponatremia is particularly likely to occur in the elderly patient with cardiac failure, since the elderly patient usually has a low reserve kidney.

Although water excretion by the kidney in heart failure is generally regarded as normal except insofar as water is retained secondary to sodium, there is evidence that, especially in advanced stages of heart failure, a water load is poorly excreted. Whereas the restricted sodium intake tends to balance the minimal sodium excretion, there is usually no restriction of fluid intake to balance the impaired water excretion. The retained water then dilutes the extracellular sodium and induces hyponatremia. This type of dilution hyponatremia due primarily to water retention while the external balance of sodium is unchanged resembles somewhat the clinical situation in water intoxication.[44] The impairment of water diuresis may be due to increased secretion of the antidiuretic hormone (ADH) in advanced refractory heart failure rather than to renal impairment, as suggested by the similarity of the clinical picture induced by administration of pitressin tannate in oil in patients with heart failure[150] on a liberal water but very restricted sodium intake.

Another factor in these cases of dilution hyponatremia is the state of the circulation, more specifically the advanced stage of congestive heart failure. The refractoriness of the heart failure is a characteristic feature and is commonly attributed to the electrolyte disturbance. Often, however, the sequence of events indicates that the unresponsiveness to therapy, especially to mercurial diuretics, as well as the abnormal electrolyte pattern is secondary to more fundamental widespread cellular disturbances which are primarily due to the advanced and virtually irreversible stage of failure of the heart and circulation.

Clinical Features. The clinical features listed as part of the low sodium syndrome include (1) gastrointestinal symptoms—anorexia, nausea, vomiting; (2) neurologic symptoms—apathy, drowsiness, restlessness, con

fusion, convulsions, coma, (3) muscular—weakness, cramps, (4) circulatory—tachycardia, shock, (5) laboratory findings including hyponatremia, hypochloremia, acidosis, rising blood urea, oliguria, low urine sodium chloride. Although thirst is commonly mentioned as one of the symptoms, it is almost always absent. Thirst occurs with dehydration, not with the low sodium syndrome. The symptoms of hyponatremia due to sodium depletion differ somewhat from those attributed to dilution hyponatremia. Weakness or prostration and muscle cramps are fairly common after excessive mercurial diuresis, presumably due to sodium depletion. With more intense diuresis, and especially after removal of pleural and ascitic fluid, the clinical picture of shock may develop in association with evidence of uremia. On the other hand the clinical picture associated with the dilution type of hyponatremia often develops more insidiously. Anorexia and apathy are early symptoms. There is a poor diuretic response to mercurial diuretics. Nausea and vomiting occur and the patient is drowsy much of the day. There is progressive oliguria and azotemia while edema persists or increases despite treatment. Severe mental symptoms with psychosis, confusion, coma and death may occur. There is increasing uremia in advanced stages of the syndrome.

It is apparent that many of the clinical features attributed to the so called low sodium syndrome are non specific and could be due to other disturbances or complications frequently observed in congestive heart failure. There is often great uncertainty as to whether the symptoms attributed to hyponatremia in heart failure are not actually due to concomitant pulmonary embolism, digitalis intoxication, primary renal disease, acute myocardial infarction, internal bleeding from anticoagulants, intercurrent infection or intractable and often irreversible heart failure.

Treatment When hyponatremia is due to sodium depletion, treatment consists in increasing sodium intake by mouth in mild cases, or administering hypertonic sodium chloride (300 cc of a 3% or 5% solution) intravenously, when the need is more urgent or the patient is unable to take the sodium orally. In the presence of significant acidosis 5 per cent sodium bicarbonate or 1/6 molar sodium lactate may be administered. Vigorous efforts to raise the sodium concentration to normal involve risk of increasing anasarca and acute pulmonary edema. The isolated occurrence of muscle cramps following a mercurial diuretic can usually be prevented by the administration of 0.3 gm of quinine on the day of the injection.

When hyponatremia is of the dilution type one should consider carefully other possible causes for the clinical picture than hyponatremia, even when the latter is present. Overdigitalization should be corrected and a careful survey made as discussed under the management of intractable heart failure. In these cases it is my present policy to restrict fluid (as well as sodium) almost as stringently as in cases of acute oliguria due to toxic nephrosis (lower nephron nephrosis). The administration of sodium orally or intravenously is contraindicated. Although the concentration of plasma sodium may be elevated and the abnormal electrolyte pattern restored toward normal by this means, and although there is rarely an equivocal clinical improvement, the latter is temporary and does not alter the usually fatal clinical course.[334] Recently Laragh[96] reported small to striking increases in serum sodium concentration when potassium chloride (4–22 gm daily of a 20% solution) was administered orally to patients in heart failure with hyponatremia. Despite the rise in sodium concentration there was no significant diuresis. It was postulated that serum sodium concentration was elevated by a release of sodium from the cells in exchange for potassium. The danger of hyperkalemia should be considered because of the inability of many cardiac patients to metabolize or excrete potassium normally.

Diuresis Hypochloremia with Alkalosis and Hypokalemia[296, 310, 312, 294] Repeated mercurial diuresis may cause three types of response with respect to blood electrolytes. (1) Mercurial diuresis and associated body adjustments usually result in no significant disproportion between loss of sodium and loss of water. Disproportionate chloride loss is promptly adjusted. In such cases of heart failure there is no important change in blood electrolyte pattern due to the mercurials. (2) Occasionally, mercurial diuresis in conjunction with low sodium intake and other factors which are incompletely understood may cause a loss of sodium disproportionate to

the loss of water or it may cause renal impairment of response to normal water intake In either circumstance hyponatremia results (3) The third and most characteristic response to mercurial diuretics is an excretion of chloride in excess of sodium relative to their concentrations in the plasma The excess of chloride is excreted with potassium ammonium or both When mercurial diuretics are repeated frequently and the diuresis is profuse striking changes in blood electrolytes may occur These consist of a marked reduction in plasma chloride (below 90 mEq per liter) with little or no reduction in plasma sodium an increase in plasma bicarbonate and in pH (alkalosis) A reduction in plasma potassium may result from the additional excretion with chloride The total pattern is described as hypochloremic alkalosis with hypokalemia In some cases of pulmonary disease with carbon dioxide retention (respiratory acidosis) there is a similar pattern with regard to elevation of bicarbonate and reduction of plasma chloride concentration This pattern may be distinguished by the low pH and clinically by the history of pulmonary disease as contrasted with the history of profuse and frequent diuresis following the injection of mercurials Diuresis hypochloremia following mercurials resembles the electrolyte pattern observed as a result of vomiting (of hydrochloric acid in gastric contents) in cases of pyloric stenosis or other conditions with profound or prolonged emesis Hypochloremic alkalosis in heart failure is most likely to follow mercurial diuresis if anorexia prevents replacement of excreted chloride and especially if there is associated vomiting e g due to digitalis toxicity On the other hand if ammonium chloride is administered in conjunction with mercurial diuretics excessive chloride loss may be replaced and hypochloremia avoided

The hypochloremic alkalosis due to mercurial diuresis may be significant clinically in two respects (1) It often interferes with further diuresis in fact mercurial unresponsiveness should suggest hypochloremia as one of the possible causes Diuresis probably depends on a specific inhibitory effect of the mercurial on the tubular reabsorption of chloride an effect which may be minimal when plasma chloride falls to low levels and when there is a markedly decreased quantity of chloride filtered by the glomeruli (2) If hypochloremic alkalosis is severe it may be responsible for clinical symptoms characterized by refractory heart failure apathy anorexia weakness drowsiness mental confusion and uremia The clinical features other than the chemical findings resemble those associated with hyponatremia

Diuresis hypochloremia with alkalosis may be corrected by the administration of chloride ion in acidifying agents such as hydrochloric acid or ammonium chloride The ammonium ion is metabolized and the free chloride ion has the same effect as hydrochloric acid If the patient can take oral medication he is given 6 to 9 gm of ammonium chloride daily in tablet form If he is intolerant to this or if urgent treatment is indicated ammonium chloride is administrated intravenously in a 1 per cent solution in 5 per cent glucose in water Because of the toxicity of the ammonium ion in high concentration (convulsions shock and death) the ammonium chloride must be given slowly not exceeding 100 cc per hour and not more than 1500 cc daily Potassium may have to be added if there is a significant hypokalemia There is evidence that when potassium salts are administered to patients with hypochloremic alkalosis calcium should also be given to avoid tetany [106]

Potassium Depletion The potassium depletion which may be caused by mercurial diuresis may be enhanced also by the use of other agents employed in the therapy of heart failure Continuous ammonium chloride therapy increases potassium excretion in combination with the additional chloride ions The tendency of cationic exchange resins to cause potassium depletion by binding potassium and increasing its fecal excretion has been discussed When Diamox is used as a diuretic alone or in combination with mercurials potassium excretion is increased along with the increase in bicarbonate excretion All these factors are rarely responsible for clinical symptoms unless the intake of potassium is poor In digitalized patients mercurial diuretics may be responsible for digitalis toxicity, especially disturbances in rhythm presumably because the mercurials cause potassium depletion (p 274) Treatment of potassium depletion consists of the administration of 2 gm of potassium chloride three times daily

orally or 3 gm of potassium chloride (40 mEq) in 1000 cc of 5 per cent glucose in water intravenously

Hyperchloremic Acidosis Other electrolyte disturbances may occur in patients receiving mercurial diuretics due not to the mercurials but to other diuretics or to resins which are being used simultaneously Thus hyperchloremia with acidosis (p 284) may occur as a result of ammonium chloride or resin therapy or as a consequence of the carbonic anhydrase inhibitor Diamox The e disturbances may modify the electrolyte changes due to the mercurials

The Administration and Dosage of Mercurial Diuretics

The soluble organic mercurial diuretics may be administered intravenously intramuscularly subcutaneously orally, by rectal suppo itories or intraperitoneally Mercuhydrin Thiomerin Mercuzanthin (mercurophylline) and Salyrgan theophylline are those in common u e They are equally effective as diuretics but it appears that Mercuhydrin and Thiomerin are least apt to cause local irritation after intramuscular injection The mercurials should be administered in the morning if possible in order that most of the diuresis is completed before the patient retires for the night

Usually I begin with an intramuscular (gluteal) injection of 0 5 cc (8 minims) to test the patient s sensitivity If this causes headache fever gastric disturbances or a rash I change to another mercurial which may be better tolerated If there are no untoward symptoms after this preliminary injection and no significant diuresis results I administer 1 cc (15 minims) of the medicament in 24 to 48 hours depending on the urgency of the ca e This dose is usually adequate for continued diuretic action and should be repeated according to need Two cubic centimeter do es produce a more profuse diuresis and may be preferable but the increa e in urinary output is le s per cc of the drug [44] On rare occasions 3 to 4 cc doses may be effective when the smaller doses have failed After the first test do ■ intramuscularly, I may administer the injection intravenously or intramuscularly depending on the degree of irritation cau ed by the latter and the ease of intravenous administration The importance of careful intravenous injections and avoidance of infiltrating the perivenous tissue has b noted All intravenous injections must given *slowly*

A nonedematous area should be chosen intramuscular injection so as to permit a sorption Usually the injection is given in t upper and outer quadrant of the buttoc When the patient is obese the needle shou be of sufficient length to reach the muscul tissue Sometimes the injections cause painfu nodular infiltrations For this reason it may l desirable to add 1 cc of 1 per cent procaine t the mercurial solution before injecting it int the muscle or Dicurin procaine may be trie If intramuscular injections are ineffective, i is always wise to switch to the intravenou route Following such a change in procedure, have several times observed an effective di uresis after the intramuscular injection ha been impotent

Because it appears that Thiomerin Mercuhydrin and perhaps other mercurials may be given subcutaneously with relatively little pain or other reaction, it has been recommended that cardiac patients be taught to give their own injections just as diabetics self administer insulin [301] However, this may be permissible only if one is certain that a given patient s state of heart failure is quite stabilized The need for careful observation of the patient in heart failure who requires mercurial injections is such as to preclude self administration in most cases

Frequency of Injections The frequency of mercurial injections depends on the clinical course and the patient's response A thorough elimination of all edema fluid, obvious and latent in the pulmonary as well as systemic tissues is the desired objective A daily record of the patient s weight, carefully determined is the most useful guide to control of his retention of fluid A record of intake and output of fluids may al o be useful but only if these are carefully ob erved Gold[143] recommends the administration of a daily mercurial diuretic in combination with other therapeutic measures until the patient's "dry" or basal weight is obtained (This is rarely necessary and may be hazardous) Thereafter the injections are spaced at intervals which will prevent fluid retention Obviously, the more rigid the limitation of sodium intake the less often or the less likely the need for the diuretic In practice mer

curial diuretics are administered between twice weekly and once in two weeks However, the frequency of injections should be individualized for each patient as determined by symptomatology and clinical examination as well as weight It is rarely desirable to *cause daily weight losses exceeding 2 to 3 pounds* if symptoms of dehydration and prostration are to be avoided

Mercury Fastness. Enhancement of Mercurial Diuresis Patients in heart failure sooner or later become unresponsive to mercurial diuretics This state has been termed "mercury fastness" Usually this is observed in the end stages of failure and after numerous injections of mercurials This unresponsiveness has been attributed to low glomerular filtration and the consequent small quantity of sodium reaching the tubules [344, 85] Thus this small quantity of filtered sodium can be completely or almost completely resorbed despite the action of the mercurial The administration of sodium might restore a mercurial diuresis but more sodium will be retained than is excreted Mercury fastness has also been ascribed to chloride depletion caused by preceding mercurial injections If the mercurial is regarded as causing diuresis by *inhibiting tubular reabsorption* of the chloride ion then chloride depletion by mercurials and diminished glomerular filtration of chlorides may result in almost complete tubular reabsorption of chloride despite the mercurial However neither explanation accounts for all the features of mercury fastness Adrenocortical activity may also contribute to mercury fastness by enhancing tubular reabsorption of sodium [347] It is probable that more fundamental processes associated with advanced heart failure are responsible for the unyielding sodium and water retention All the factors which may contribute to refractory heart failure *may be concerned also in mercury fastness* including pulmonary infection or embolism under or overdigitalization disturbances in electrolytes and so forth The simultaneous exhibition of drugs with antidiuretic effect may impair the response to mercurials e g morphine Demerol and related drugs [1] barbiturates, pitressin and adrenocortical and other sodium retaining hormones

A variety of agents have been employed to enhance the diuretic response to mercurials Ammonium chloride (p 284) is employed most commonly A common procedure is to administer 2 to 3 gm in tablet form, orally, three or four times daily, for two days prior to the injection of a mercurial Aminophylline may be administered intravenously (0 25–0 5 gm) *one or two hours after the mercurial is injected* or 0 5 gm may be mixed with the mercurial [35] This may be given in addition to ammonium chloride preceding the mercurial Decholin (sodium dehydrocholate) ascorbic acid and more recently pyridoxine [347] (100 mg) have been administered intravenously together with the mercurial in order to potentiate the effect of mercurial diuretics Occasionally Diamox (p 282) has been effective in activating mercurial diuresis after the patient appeared refractory In most patients with heart failure who require mercurial diuretics I have found no need for ammonium chloride or other potentiating adjuvants If diuresis is satisfactory with a dose of 2 cc of the mercurial but clinical progress appears inadequate I increase the frequency of injections rather than the dose of the mercurial and rather than adding diuretic adjuvants At the same time of course the *proper administration of all other therapeutic agents* is essential All the adjuvants are tried only if there is no definite diuretic response to the mercurials Ammonium chloride is also given if frequent mercurial diuresis is responsible for chloride depletion and hypochloremic alkalosis

ORAL DIURETICS MERCURIALS AND CARBONIC ANHYDRASE INHIBITORS

It would be highly desirable to obtain a diuretic agent which could be given orally and yet act as effectively as parenterally administered mercurial diuretics without producing significant toxic manifestations No available *oral diuretic* satisfies this objective When the cardiac patient appears to become refractory to parenterally administered mercurials there is often a desperate trial to substitute other diuretics in the hope of greater effectiveness this is virtually futile On the other hand if the advantage of *oral* versus *parenteral administration* is the chief objective and if some sacrifice of potency and speed of action is permissible then oral diuretics now available may be employed with gratifying therapeutic effectiveness in many patients with congestive

heart failure. When effective, such oral diuretics offer the advantages of continuous instead of intermittent diuresis, avoidance of injections or diminution of their frequency, and reduction in the number of visits to the physician by ambulant patients who do not otherwise require such continuous clinical observation.

Oral preparations of Salyrgan-theophylline, mercuzanthin and Mercuhydrin, also in combination with ascorbic acid,[39] have been long available in tablets containing about 30 mg of mercury or slightly less than the amount in 1 cc of the parenteral preparation. Various dosage schedules have been employed, such as two or three tablets each morning after breakfast, one tablet three times daily, or five tablets in a single dose every few days. Although these preparations have produced a satisfactory diuretic response in many patients,[40] they have not gained any significantly widespread acceptance in clinical practice because of inadequacy or uncertainty of diuretic effect and a relatively high incidence of toxic manifestations. The latter include, most commonly, abdominal cramps with or without diarrhea, nausea, painful gums or albuminuria and other evidences of mercurialism.[88] For this reason adequate frequent supervision by a physician is necessary.

Neohydrin. Efforts have continued to produce more effective oral mercurial diuretics with greater potency relative to toxicity.[155, 19] Currently the most promising is *Neohydrin* (chlormerodrin) (3-chloromercuri-2-methoxypropylurea), which is available in tablets containing 10 mg of mercury, compared with 30 mg in most of the other oral mercurial tablets. It is claimed that Neohydrin has three to five times the potency of oral Mercuhydrin[155] and hence the lower mercury content needed per tablet of Neohydrin. Various observers have reported that Neohydrin produces a satisfactory natriuresis and diuresis almost comparable to that of a mercurial administered parenterally in about two thirds or three quarters of patients with congestive heart failure,[114] and further that 50 to 90 per cent of cardiac patients can be treated as well with Neohydrin as with parenteral mercurials.[45, 4, 189, 90] Administration is begun with one to three tablets given in a single dose in the morning or in divided doses. The dosage is gradually increased over a period of weeks, as required to obtain a satisfactory diuresis without unpleasant or toxic reactions. Frequently the effective dosage is five to eight tablets daily (equivalent to 1 to 2 cc Mercuhydrin by injection twice a week), but the higher and more effective doses are accompanied by the highest incidence of side actions. Some patients report a satisfactory result with one or two tablets daily. In such cases it is desirable to review critically the need for any diuretic. However, after a satisfactory control of heart failure is attained, a lower maintenance dose may be more effective then the dose needed to achieve initial control. Toxic reactions, usually nausea or other gastrointestinal disturbancs, are encountered in 15 to 25 per cent of cases, but discontinuation of the drug because of these side actions is necessary in only about 10 per cent of the cases. In general, it appears that Neohydrin is more effective and produces significantly fewer reactions than any of the previously available oral mercurial diuretics.

Nevertheless, nothing in this section should be construed to indicate any enthusiasm on my part for Neohydrin or indeed any currently available oral diuretic. None of them are in a class with the parenterally administered mercurial diuretic. Almost always in clinical practice I either administer a mercurial diuretic parenterally or find no need for any diuretic. In ambulant patients with mild congestive heart failure receiving weekly injections of mercurials, Neohydrin may serve to diminish the frequency of injections or entirely obviate their use. But in many, if not most, such cases it will be found that the injections can be diminished in frequency or eliminated without the substitution of Neohydrin, especially if careful attention is paid to other therapeutic measures.

Diamox. Interest has centered on a group of non-mercurial compounds, the carbonic anhydrase inhibitors, which act as diuretics by inhibiting the tubular reabsorption of sodium and water, but by a different mechanism from that involved in mercurial diuresis. *Diamox* (acetazoleamide) (2-acetylamino-1,3,4-thiadiazole-5-sulfonamide), one of the most potent carbonic anhydrase inhibitors and of remarkable low toxicity, causes a significant diuresis of sodium, potassium, bicarbonate and water when administered intravenously[134] or orally.[134] There is little effect on chloride or phosphate excretion, but urinary excretion of titratable acidity and am

monia is abolished and the urine is rendered alkaline.[133] Diuresis begins about an hour after oral administration of Diamox, reaches a peak in two hours and is completed within five to eight hours. If the drug is repeated at eight hour intervals, the diuretic effect diminishes progressively, and if continued each day it becomes virtually ineffective after three days, possibly because of the development of acidosis and more particularly a low plasma carbon dioxide tension.[133, 134, 233] The ingestion of Diamox greatly increases the rate of maximal water diuresis.[144, 75]

It is generally accepted that the conservation of sodium and development of an acid urine is dependent on the activity in the tubule cells of the enzyme carbonic anhydrase. This promotes the formation of carbonic acid from water and carbon dioxide, whereupon the carbonic acid dissociates and releases H^+ which is secreted into the tubule lumen in exchange for sodium ion.[1, 2] By inhibition of the activity of carbonic anhydrase and thereby the formation of carbonic acid, hydrogen secretion is greatly diminished and sodium reabsorption reduced. Since K^+ and H^+ compete for the tubular mechanism by which these ions are secreted, reduction in H^+ secretion increases K^+ secretion.[23] The increased Na^+ and K^+ excretion also results in a diuresis of water. These cations are excreted chiefly with bicarbonate because the absence of H^+ abolishes the normal conversion of bicarbonate ions to carbonic acid, which is reabsorbed as carbon dioxide.

Diamox is now available as a 250 mg. tablet for oral use. Its dose is about 5 mg. per kilogram body weight, but usually one or occasionally two tablets are effective. A single dose is administered daily in the morning and the diuresis is completed within eight hours. Responsiveness is usually reestablished by the next day. To avoid refractoriness I have frequently prescribed Diamox once daily for three days and omission on the fourth day, or once daily and omission on the sixth and seventh days. Side actions have occurred very infrequently and have rarely necessitated discontinuation of the drug. Drowsiness, lassitude and paresthesias were noted occasionally but disappeared when the drug was discontinued. Blood electrolyte changes which may be induced are hyperchloremic acidosis and hypokalemia, but these are mild with therapeutic dosage.[134] The reduction in plasma bicarbonate inhibits further diuretic activity of the Diamox.

The chief value of Diamox has been found in ambulant patients receiving regular injections of a mercurial diuretic.[134, 17, 209] In such patients the frequency of injections may be diminished, and in about 80 per cent the injections may be discontinued for relatively long periods by substituting oral Diamox. Diamox is more effective in substituting for maintenance injections of mercurials than in initiating control of a severely edematous cardiac patient. Many of the comments made regarding Neohydrin apply to Diamox. Diamox possesses the advantage of less side action or toxicity. Disappointment with Diamox is sure to follow the hope that it is as effective or even almost as effective as an injected mercurial diuretic in patients with severe congestive heart failure, or the expectation of a striking copious diuresis such as one often encounters with the mercurial. The physician is especially likely to find the drug unsatisfactory if he resorts to Diamox only in cases of intractable heart failure after the patient has become refractory to parenteral mercurials. On the other hand, Diamox may be extremely helpful in some cases of intractable heart failure, not as the sole diuretic but in restoring or increasing responsiveness to a mercurial diuretic. Rubin and associates[182] described a striking restoration of responsiveness to mercurial diuretics following the production and maintenance of hyperchloremic acidosis by Diamox and ammonium chloride. Five hundred mg. of Diamox may be given daily for five days. On the fourth and fifth days 10 gm. of ammonium chloride is administered orally in divided doses and continued on the sixth day without Diamox. On the seventh day and, if necessary, for several days thereafter, a mercurial diuretic is administered intramuscularly while ammonium chloride therapy is continued. The hyperchloremia induced by Diamox and ammonium chloride accounts for the restoration of mercurial effectiveness, since the primary action of the mercurial may be on the reabsorption of the chloride ion; elevation of plasma chloride concentration may enhance mercurial diuresis, especially if the plasma chloride concentration was previously diminished by mercurial diuresis or other factors. However, when Diamox is used as a diuretic rather than as a mercurial potentiator, am-

monium chloride should not be administered as the resulting acidosis inhibits Diamox activity Diamox may also prove of special value in the cases of heart failure secondary to obstructive emphysema with cor pulmonale in which there is a retention of carbon dioxide [53, 9] but there is disagreement as to the efficacy of Diamox in such cases [71]

ACIDIFYING SALTS

Ammonium chloride, ammonium nitrate and calcium chloride have been regarded as diuretics which act by causing acidosis [137] In my experience these substances, when employed alone are of no practical value as diuretics in the treatment of heart failure I have employed ammonium chloride only as an adjuvant preliminary to the administration of mercurial diuretics and then only infrequently There is evidence that the potentiation of mercurial diuresis by ammonium chloride[186] is not due or not entirely due to the production of acidosis [200] Hilton[180] observed that the potentiating diuretic effect of ammonium chloride on a mercurial in normal subjects was independent of the presence of acidosis or of its intensity The potentiating effect of ammonium chloride on mercurials has been attributed to the chloride ion rather than to its acidotic effect The ammonium ion is metabolized by the liver while the excess chloride or nitrate then carries sodium with it and consequently a corresponding quantity of fluid is excreted Ammonia production through ammonium producing enzymes such as glutaminase, is a regulatory response to ingested acid substances but lags the first two days During this initial period acidic salts are most likely to be effective in increasing sodium excretion [285] After three or four days increased glutaminase activity produces increased ammonia [88, 26] which then can combine with the chloride or other acidic ion and thus conserves sodium

Two to 3 gm (30 to 45 grains) of ammonium chloride three times daily are often administered orally for the two days preceding each injection of Mercuhydrin This is given in the form of compressed tablets of 0 4 gm (6 grains) each (i e five to eight tablets three times daily) or of keratin coated capsules of 0 5 gm (7½ grains) each (four to six tablets three times daily) In the intervals the ammonium chloride is discontinued to avoid nausea, vomiting or severe acidosis The acidifying salts are contraindicated in patients with renal impairment Prolonged use of ammonium chloride with the mercurials may cause potassium depletion and hypokalemia Occasionally I have seen prolonged use of ammonium chloride cause severe acidosis with intense dyspnea which was mistaken for the dyspnea of intractable heart failure The clinical picture is characterized by anorexia, nausea, vomiting, lassitude progressing to marked stupor, areflexia and Kussmaul respiration [26] and may simulate a cerebrovascular accident [30] The blood plasma shows an elevated chloride and reduced bicarbonate (hyperchloremic acidosis) (see Fig 61) and moderate azotemia A similar blood electrolyte spectrum is produced by cationic resins and Diamox Hyperchloremic acidosis from ammonium chloride therapy is most apt to occur in the presence of intrinsic renal disease as indicated by constant, marked albuminuria and a fixed low specific gravity Hyperchloremic acidosis is treated by the intravenous administration of isotonic (5%) sodium bicarbonate or ⅙ molar sodium lactate

XANTHINE DERIVATIVES

The xanthine derivatives (purines) are now of limited use as diuretics because of their uncertain effectiveness and the decisive superiority of the mercurial salts The xanthine derivatives may be worthy of trial when the mercurials are not tolerated They possess the advantage that they may be taken orally The exact mode of diuretic action of the xanthines is uncertain—increase in glomerular filtration decrease in tubular reabsorption, increased blood flow and other mechanisms having been invoked [37, 41, 201] Following the intravenous administration of aminophylline to 45 patients with myocardial insufficiency Green and associates[11] observed an average increase in cardiac output of 12 per cent with a range of plus 185 to minus 45 per cent There was a more impressive increase in sodium and water excretion, especially the former Renal clearance data indicated that the heightened excretion of sodium was due to a diminution in tubular reabsorption of this ion Similarly Davis and Shock[31] noted a variable increase in renal plasma flow and glomerular filtration rate with a more prominent and sustained increase in sodium clear

ance They therefore concluded that the latter was a result of a decreased tubular reabsorption of sodium

The most effective diuretic of this group is theophylline (Theocin)[187] while theobromine theobromine sodiosalicylate (Diuretin) and caffeine have weaker actions Theophylline ethylenediamine (aminophylline) in doses of 0 1 to 0 2 gm three or four times daily Theocalcin (theobromine calcium salicylate) in doses of 1 0 gm four times daily Theesodate (theobromine sodium acetate) in doses of 0 5 gm four times daily and theophylline (Theocin) 0 2 gm four times daily are among the commonly employed xanthine diuretics But the effectiveness of aminophylline administered orally is unpredictable because of uncertain absorption or its destruction by the liver For this reason rectal administration by suppository and especially intravenous injection have been employed to circumvent the liver and these routes of administration are more effective Choline theophyllinate in doses of 50 to 400 mg (average 200 mg) three or four times daily was reported to abolish the need for mercurials or reduce their frequency at least 50 per cent in 28 out of 45 patients with congestive heart failure[3] Except in very occasional instances I have found no need for the xanthine diuretics when the mercurials can be used However the intravenous administration of aminophylline (0 25 or 0 5 gm in 10 cc) is very effective in controlling Cheyne-Stokes respiration associated with heart failure and aminophylline suppositories containing 0 3 to 0 5 gm of aminophylline inserted before retiring sometimes help to avoid paroxysms of nocturnal dyspnea The control of Cheyne-Stokes respiration by aminophylline is not due to increased cerebral blood flow as was formerly believed since actual measurements by the nitrous oxide method revealed that aminophylline depressed cerebral blood flow[249] It has been suggested that aminophylline stimulates the respiratory center directly or indirectly by increasing the medullary carbon dioxide

Headache nervousness nausea and vomiting abdominal cramps and diarrhea are common symptoms of sensitivity to the xanthine derivatives especially if given in full therapeutic doses Epilepsy is a contraindication to these drugs as they are said to irritate the cerebral cortex and precipitate convulsions in susceptible individuals Sometimes the toxic symptoms of the purines can be prevented by combining each dose with ¼ to ¾ grain of phenobarbital

URACILS

The uracils are related compounds (ureide dihydroxypyrimidines) which have been investigated as possible oral diuretics While some of them have produced a satisfactory diuretic effect in cardiac patients[175, 191] presumably by inhibiting tubular reabsorption of sodium[191] they have not gained clinical acceptance chiefly because of the high incidence of gastrointestinal and other symptoms[191] One of the uracil derivatives Mictine (brand of aminometramide), has been recently made commercially available in 200 mg tablets It is recommended in doses of four to six tablets daily with meals for initial and continuing diuresis and one to four tablets daily for maintenance

UREA

When renal function is intact and other diuretics are no longer effective or cannot be given urea is sometimes of distinct value as a diuretic Satisfactory results have been reported by Miller and Feldman[48] who administered urea for long periods to the same patients Important objections to this substance are the nauseating taste and the tendency to cause vomiting or extreme thirst I have seen excellent clinical results on occasion but have utilized it rarely in recent years

Large doses of urea (45 to 90 gm daily) must be given usually in divided doses two to four times daily Various efforts not too successful have been made to disguise its taste It has been given in ice cold water in grape juice in beer and in mixtures containing syrup of acacia I have found urea to be taken best as an effervescent mixture made as follows

℞		gm or cc
Urea	℥ xvi	480 0
Saccharin	gr vi	0 7
Potassium bicarbonate	℥ xii	48 0
Citric acid	℥ xiii ss	55 0
Tartaric acid	gr xxx	2 0
Oil of peppermint	gtt vi	0 4

M Sig One or two ounces dissolved in water three times daily Drink slowly while effervescing

POTASSIUM SALTS

Potassium salts have been used as diuretics, especially in combination with restriction of sodium chloride and fluids [193] They are contra indicated in the presence of renal insufficiency There is also evidence that patients with severe heart disease do not handle a potassium load normally [47] Therefore there is some risk in inducing dangerously high plasma potassium levels Potassium chloride is usually given in doses of 2 to 4 gm three times daily To avoid gastric irritation it is usually given in enteric coated tablets The cardiac toxicity of potassium salts is discussed on page 1030

ALCOHOL[250]

Alcohol has a specific diuretic action, probably the result of decreased secretion of antidiuretic hormone since alcohol diuresis is inhibited by pitressin [100] In addition water and other liquids taken with alcohol account for some of the diuretic effect

OTHER DRUGS

Morphine

Next to digitalis and the mercurial diuretics morphine is the most useful drug in the treatment of congestive heart failure Its chief value and indication are in the management of the acute episodes associated with heart failure Under such circumstances the therapeutic benefits of morphine are often brilliant and appear with striking speed Morphine is administered for the relief of various forms of dyspnea, especially cardiac asthma and pulmonary edema but also for severe dyspnea at rest and orthopnea associated with left sided heart failure Each dose of morphine should be individually ordered by the physician Standing orders for repeated doses of opiates occasionally lead to serious overdosage or addiction When dyspnea becomes persistent, the danger of morphine addiction must always be borne in mind, the drug must be either withheld or administered in small doses of 0 007 to 0 010 gm (1/8 to 1/6 grain) Often these doses accomplish as much as can be expected from the use of morphine in cases of congestive heart failure Even when care is exercised morphine addiction is not rare because the unequalled though temporary, relief attained with this medicament leads to its continued usage

The action of morphine, in so far as it relieves the symptoms of congestive heart failure, is not altogether certain In the first place it depresses the respiratory center and interferes with the reflex which causes hyperventilation and dyspnea (see p 191) At the same time it probably reduces the venous return to the heart, thereby diminishing the output of the right ventricle and consequently also the intense pulmonary congestion which is the basis of dyspnea The diminution in ventilation reduces the work of the respiratory muscles The elimination of the patient's restlessness and anxiety is also an important effect of morphine serving to improve the patient's comfort On the unfavorable side is the antidiuretic effect of morphine in patients with heart failure,[11] but this is rarely of practical importance

If the patient is suffering from moderate continuous dyspnea at rest and orthopnea he should be given 0 010 gm (1/6 grain) of morphine or 5 minims of a 3 per cent aqueous solution hypodermically This should be repeated morning and evening for a day or two until rest, digitalis and diuretics become effective If the dyspnea is acute or severe, the dosage may have to be increased to 0 015 gm (1/4 grain) or 0 5 cc (7½ minims) of the 3 per cent solution If the patient is experiencing an attack of cardiac asthma or acute pulmonary edema the dose should be between 0 015 and 0 020 gm (1/4 to 1/3 grain), depending on the severity of the attack If immediate relief is urgent, the morphine should be given intramuscularly or 0 010 gm (1/6 grain) should be injected intravenously, since the effect of morphine administered subcutaneously may not appear for one half hour or more If the patient had been suffering from recurrent attacks small doses of morphine may be given prophylactically for a few days, usually before the patient retires in the evening As a rule, 0 006 to 0 010 gm (1/10 to 1/6 grain) of morphine hypodermically or 0 010 to 0 015 gm (1/6 to 1/4 grain) by mouth will suffice But this is rarely necessary if digitalization sodium restriction mercurial diuretics and oxygen therapy are properly employed Meperidine (Demerol) is useful for analgesia, but does not depress the respiratory center in therapeutic doses and therefore is not a substitute for morphine in the relief of dyspnea

Codeine

Codeine sulfate in doses of 0 03 to 0 06 gm (½ to 1 grain) hypodermically may oc

casionally be substituted satisfactorily for morphine in treating patients with chronic dyspnea. The chief value of this drug, however, is to control the cough due to pulmonary congestion and infection. The dose is 0.015 gm (1/4 grain) by mouth every three to four hours, but larger doses may be needed. Hycodan bitartrate in doses of 0.005 to 0.01 gm (1/12 to 1/6 grain) is at least as effective in controlling cough and is less constipating than codeine. The medication should be given at night or repeated throughout the day if necessary.

Sedatives

Bromides in doses of 10 to 15 grains three times daily, chloral in doses of 5 to 15 grains, or combinations of the two in smaller dosage, or phenobarbital in doses of 0.015 to 0.03 gm (1/4 to 1/2 grain) three times daily are valuable as sedatives to allay restlessness and anxiety. Soporifics such as Nembutal (1½ to 3 grains), Seconal (1½ to 3 grains), Ipral (2 to 4 grains) or Veronal (5 to 10 grains) may be necessary to induce sleep. If insomnia is due to cough, codeine is necessary, either in place of or in combination with soporifics.

Antibiotics

Bronchopulmonary infections occur commonly in the congested lungs of patients with heart failure. They often account for the unexplained fever observed in many cases of heart failure, but it may be difficult to distinguish the signs of congestion from those of pneumonia. The use of antibiotics is often justified on an empiric basis in patients with heart failure who are febrile or experience cough out of proportion to the degree of pulmonary congestion, especially if the cough is not relieved by antidiuretics. The incidence of pulmonary infection as a contributory or primary cause of death in heart failure has diminished greatly since the widespread employment of antibiotics. Because of these observations it has been suggested that broad spectrum antibiotics be administered prophylactically for prolonged periods to patients with heart failure, especially old people.[237]

Dicumarol

This drug has been administered in order to reduce the frequency of thromboembolic complications in heart failure and beneficial results have been reported.[255] (For method of administration see p. 577.) Patients with congestive heart failure, especially those subjected to prolonged bed rest, are particularly susceptible to venous thrombosis and pulmonary emboli. If the reported favorable results of anticoagulants in the treatment of acute myocardial infarction may be applied to cases of congestive heart failure, anticoagulants should be equally effective in heart failure. Several reports of controlled series of cases of heart failure[267, 2, 359] treated with and without anticoagulants have indicated that the incidence of thromboembolic complications and the mortality rate in those patients receiving anticoagulants were reduced by as much as one third to one half of those in control patients. Because of impaired hepatic function in congestive heart failure (p. 151), the prothrombin time is often prolonged and the patient may be excessively sensitive to anticoagulants. Therefore, the prothrombin time should be determined before anticoagulants are administered as well as repeatedly during anticoagulant therapy. Although anticoagulants would appear to be of promising value in congestive heart failure, the difficulty of convincing many physicians of their value in myocardial infarction despite impressive statistical evidence in their favor suggests that it will be even more difficult to obtain convincing evidence of their benefit in heart failure.

Hypotensive Drugs

Ganglion blocking hypotensive drugs used in the treatment of hypertension were noted to ameliorate associated congestive heart failure.[57] A reduction in pulmonary congestion and dyspnea and an increase in vital capacity were noted, as well as a diminution in cardiac size and improved exercise tolerance after the administration of pentamethonium to hypertensive patients with heart failure.[303] Kelley et al.[195] reported that the slow intravenous administration of 30 mg of hexamethonium in 19 patients with various types of heart disease and heart failure reduced the elevated venous pressure as well as the right atrial, right ventricular and pulmonary arterial pressures, shortened the circulation time and effected symptomatic improvement in the degree of dyspnea and orthopnea. They suggested that the beneficial action of hexamethonium in heart failure was due both to a diminution in peripheral resistance, reducing the work demand of the left ventricle, and to a lowering of the filling pressure of the right heart, permitting it to contract more effectively. Similar observa

tions were made by Shuman and associates[299] in 21 patients with congestive heart failure due to hypertension, coronary arteriosclerosis and valvular heart disease, following the administration of tetraethylammonium bromide and hexamethonium iodide Hexamethonium may also be useful in the treatment of paroxysmal dyspnea or pulmonary edema in patients with mitral stenosis and pulmonary hypertension, since it may reduce the pulmonary artery pressure without diminishing the cardiac output [79, 104a]

Laxatives and Cathartics

When patients are ambulant regular bowel action should be induced by habit formation with or without the aid of mineral oil If this does not succeed or if patients are confined to bed it is necessary to maintain regular bowel movements by mild cathartics or laxatives Milk of magnesia (1 to 2 oz), cascara sagrada (5 to 10 grains) or compound licorice powder (2 to 3 teaspoonfuls) is usually adequate Magnesium sulfate (½ oz), given every few days has been found useful when patients are edematous due theoretically to the loss of fluids associated with the catharsis Cathartics acting on the colon should not be administered to patients receiving oral mercurial diuretics (see p 282) The possibility of potassium depletion due to drastic catharsis should be considered Occasionally glycerin suppositories or small oil saline or sodium bicarbonate enemas are useful, but they should be avoided if they weaken the patient unduly An occasional colon irrigation when properly performed tires the patient less than an enema and relieves abdominal distention as well as constipation Some patients undergo more physical and mental strain in trying to use the bedpan than when helped to the toilet or preferably to a commode at the side of the bed For such patients the physician should employ his good judgment in determining whether the use of the bedpan is absolutely essential

Brandy sherry or nux vomica may be useful in treating patients who are depressed or suffer from weakness and anorexia The alcoholic beverages may be especially helpful for elderly patients and those with coronary heart disease

Hypertonic solutions of dextrose (50 cc of 50 per cent 125 cc of 20 per cent or 250 cc of 10 per cent solution) or of sucrose may be given intravenously in attacks of pulmonary edema and to promote diuresis The carbohydrates have also been considered of therapeutic benefit because they improve the nutrition of the heart

OXYGEN THERAPY AND POSITIVE PRESSURE RESPIRATION[57, 28]

Oxygen administered in high concentrations (40 to 50 per cent or higher), by means of special masks, tents or nasal catheter, may be of great symptomatic value in some cases of congestive heart failure According to Barach and his associates,[5] who have been the most ardent advocates of this therapeutic measure, the depressed oxygen saturation of the arterial blood is restored to normal dyspnea and cyanosis are relieved the lactic acid content of the blood is diminished diuresis effected and edema reduced In my experience oxygen therapy is of limited value for the fundamental manifestations of congestive heart failure but may be of great benefit in treating associated symptoms or complications It was shown above (p 190) that the arterial blood of patients with congestive heart failure usually has a normal oxygen saturation so that further oxygen administration has no theoretical indication in most cases But aside from any increase in the oxygen carried by hemoglobin increased oxygen concentration in the inhaled air results also in an increased concentration of oxygen dissolved in plasma and available for greater oxygen supply to the tissue Actually many patients report subjective improvement with oxygen therapy High concentrations of oxygen are indicated chiefly in the relatively small percentage of cases of congestive heart failure in which the oxygen content of the arterial blood is diminished and in patients with pulmonary edema or other associated pulmonary disease or complications Usually but not always, such cases are recognizable by the presence of cyanosis but a therapeutic trial is desirable if there is any doubt If oxygen must be administered continuously for many days, a tent is usually preferable to the mask since the administration of pure oxygen is irritating unless it is hydrated At an oxygen inflow of 8 to 10 liters per minute oxygen concentrations of 40 to 45 per cent can be maintained in the tent The air cooling effect of oxygen by tent is often beneficial in warm weather, since patients with congestive heart failure cannot tolerate excessively warm atmospheres [19]

The cases of congestive heart failure in which oxygen therapy is indicated usually include the following

(a) Congestive heart failure of rheumatic coronary atherosclerotic hypertensive or syphilitic etiology complicated by pulmonary lesions such as infarcts pulmonary edema lobar or bronchopneumonia

(b) Congestive heart failure secondary to bronchopulmonary disease such as pulmonary fibrosis of varied etiology and pulmonary emphysema in which there is no significant carbon dioxide retention

(c) Congestive heart failure associated with acute coronary thrombosis

The administration of oxygen in the ordinary manner can hardly be expected to affect the arterial blood when it is normally saturated with oxygen But the inhalation of oxygen or air under a positive pressure of 5 to 8 mm Hg may be beneficial even in such cases[4] For then the arterial oxygen content may be even greater than normal because the oxygen content of the plasma is increased the oxygen combined with the hemoglobin being of course unchanged Barach[4] reported a clearing of pulmonary edema due to heart failure presumably because the oxygen introduced offers an opposing pressure to the increased pulmonary capillary pressure and thus retards the exudation of plasma from the capillaries into alveoli The oxygen causes a positive pressure within the chest which retards the entrance of blood into the right heart and therefore into the lungs In patients with acute left heart failure diminution of the venous return may act like a phlebotomy to permit recovery of cardiac function and increase in cardiac output Helium-oxygen mixtures are often used with positive pressure breathing because of the lower specific gravity of helium *Thus much less effort is required* than for the breathing of air or pure oxygen

When oxygen is administered in concentrations of 90 to 100 per cent it is irritating to the mucosa of the respiratory tract and may induce coughing It diminishes pulmonary ventilation which may be physiologically undesirable although symptomatically advantageous In cases of heart failure due to cor pulmonale oxygen concentrations of 40 to 50 per cent may be dangerous and even fatal because the oxygen removes the needed respiratory stimulus of anoxia depresses respiration and causes elevation of the blood carbon dioxide to toxic level (p 993)

PHLEBOTOMY (VENESECTION)

The removal of 350 to 1000 cc of blood from the vein of a patient with congestive heart failure may rapidly and dramatically relieve dyspnea orthopnea cyanosis systemic venous and hepatic engorgement Phlebotomy is indicated chiefly when there is intense pulmonary engorgement (especially with pulmonary edema) due to left-sided heart failure But it is also useful in cases of right sided heart failure in which there is an extreme elevation of the venous pressure and associated manifestations of systemic engorgement Phlebotomy is often a life-saving measure when the patient suffers from acute pulmonary edema Phlebotomy should also be performed when morphine and other therapeutic measures fail to control an attack or recurrent attacks of cardiac asthma

In cases of right sided heart failure with high venous pressure phlebotomy markedly reduces the pressure and often relieves symptoms but the therapeutic results are rarely as striking as in cases of acute left sided heart failure The symptomatic improvement after phlebotomy usually occurs with incredible speed often when the needle is still in the vein For phlebotomy in cor pulmonale see page 994

The removal of less than 350 cc of blood is rarely useful, larger amounts (up to 1000 cc) should be withdrawn if no benefit is obtained especially if the patient is a large person has an increased blood volume is hypertensive and if his blood has a satisfactory hemoglobin content Phlebotomy is rarely justified if the patient is anemic The phlebotomy should be performed by introducing a needle of large bore such as is used for transfusions connected with a 6 inch rubber tube by an adapter A free flow should be obtained to avoid clotting In an emergency the vein may have to be cut with a sterile scalpel

Phlebotomy relieves the symptoms of congestive heart failure by reducing the circulating blood volume and consequently the venous return to the right side of the heart This reduces the right ventricular output into the congested lung The overloaded and failing left heart can then increase its cardiac output and relieve the pulmonary

congestion[182] In contrast to the emergency benefit of a needed phlebotomy is the subsequent regret at the loss of oxygen carrying capacity of the blood Therefore the indication for phlebotomy should be unequivocal The cautious replacement of packed erythrocytes may have to be considered after the acute disturbance has been definitely controlled

Tourniquets

Effects similar to phlebotomy may be obtained by the temporary application of tourniquets or blood pressure cuffs to all four extremities[97] Dramatic improvement may follow this procedure in cases of paroxysmal dyspnea or pulmonary edema due to acute left ventricular failure This procedure should always be tried before a phlebotomy is performed However tourniquets should be applied only for limited periods (15 to 30 minutes) to any given extremity The tourniquets on each one of the four extremities should be serially removed for brief intervals The application of tourniquets decreases the venous return and affords relief but the cardiac output may be reduced so markedly that shock is induced

MECHANICAL REMOVAL OF SEROUS EFFUSION AND EDEMA FLUID

Thoracentesis

It is often necessary to remove pleural effusions in cases of congestive heart failure Thoracentesis is indicated when the effusion is large and is causing or contributing to dyspnea It is sometimes difficult to ascertain the exact importance of a pleural effusion in the production of this symptom When other therapeutic measures fail to relieve dyspnea, the removal of fluid from the chest is often indicated even when the size of the effusion does not appear to be very large I use an airtight Potain set by means of which the effusion is removed by suction into a bottle containing a partial vacuum The patient lies on his side, with the side to be tapped uppermost The needle is introduced posteriorly near the lower end of the effusion the site of which has been localized by percussion or roentgen ray examination Usually 500 to 1000 cc but not more than 1500 cc is removed The procedure should be stopped if the patient becomes dyspneic coughs or has pain in the shoulders Repeated aspirations of fluid from the pleural space have been effective in the removal of previously resistant edema[284]

Abdominal Paracentesis

Only occasionally must ascitic fluid be removed in cases of congestive heart failure, and much more rarely since the use of the powerful mercurial diuretics Abdominal paracentesis is indicated when the peritoneal effusion is sufficient to cause symptoms such as dyspnea and distention despite all other medical therapy

The patient, after voiding sits up in bed with his feet hanging over the side of the bed onto a chair The skin of the lower half of the abdomen is cleaned and the site of injection is sterilized and infiltrated with 2 per cent procaine This site is in the linea alba midway between the umbilicus and symphysis pubis Through the anesthetized area a 1 inch incision is made with a scalpel through the skin and fascia A trocar and cannula are introduced by way of the incision through the fascia and into the abdominal cavity The trocar is withdrawn and the ascitic fluid allowed to run out of the cannula and connecting tubes into large flasks When the fluid stops draining a sterile dressing and adhesive tape are placed over the incision and a broad, tight abdominal binder is applied

Mechanical removal of subcutaneous edema is rarely necessary since mercurial diuretics have become available If essential, the surgical insertion of Southey tubes or multiple incisions of the skin and subcutaneous tissue, usually of the legs, may effectively remove large quantities of fluid[173, 314] Aseptic technique should be employed even though the danger of infection is less than in cases of nephrotic edema The prophylactic administration of penicillin is justifiable Massive edema of the scrotum should be treated by elevation with a Bellevue bridge and if necessary by multiple incisions

LIGATION OF THE INFERIOR VENA CAVA

I have formerly employed ligation of the inferior vena cava in patients with heart failure primarily to prevent pulmonary emboli arising in venous thrombi in the legs Such emboli are relatively frequent in advanced heart failure, and may be responsible for it being refractory to conventional treatment Ligation of the inferior vena cava has also been suggested[79] for its more direct beneficial effect in advanced failure Such ligation, acting as a chronic internal tourniquet, impairs the venous return and relieves the overburdened

heart which then increases its cardiac output According to Cossio and Perianes[79] the benefit of inferior vena caval ligation depends also on improved lymphatic circulation Pulmonary hypertension is said to be relieved Clinically the symptoms and signs of both left and right-sided heart failure may be ameliorated Favorable results in 55 to 65 per cent of large series of cases of heart failure treated by inferior vena caval ligation have been reported by South American and French physicians [81, [illegible], 83] In the earlier reports the mortality rate was 20 to 25 per cent but this has been substantially diminished [4] I have resorted to inferior caval ligation only occasionally since oral anticoagulants have been used extensively and since surgical procedures on the heart especially mitral commissurotomy have been available In some of the cases in which I have recommended inferior vena caval ligation for refractory heart failure associated with suspected recurrent pulmonary emboli the results were spectacularly beneficial I have always presumed that the clinical improvement was due to cessation of pulmonary embolization but it may have been due also to relief of overloading of the circulation by diminishing the venous return Ligation of the inferior vena cava may be regarded as a palliative procedure in intractable heart failure especially when accompanied by pulmonary emboli [82]

TOTAL THYROIDECTOMY ANTITHYROID DRUGS RADIOIODINE

Thyroidectomy was suggested as a means of treating congestive heart failure in the hope that by lowering the basal metabolism i e the oxygen requirement and other needs of the tissues the slow inadequate circulation would then be sufficient for the lesser demands made upon it Furthermore the cardiac output and the work of the heart would be diminished Subtotal thyroidectomy often gave brilliant results in cases associated with hyperthyroidism but was ineffective in other cases of congestive heart failure Blumgart and his associates[88] suggested and performed total thyroidectomy for the treatment of congestive heart failure (and angina pectoris for which see p 483) The operation was restricted to those patients who were reasonably good surgical risks and suffered from intolerable congestive heart failure which had not responded to any or all of the measures discussed above The results obtained have not been sufficiently striking to justify use of such a drastic operation

Thiouracil and Other Antithyroid Drugs

The same principle underlying total thyroidectomy for heart failure has suggested the use of antithyroid drugs to lower the metabolism and thus reduce the work of the heart Sharpey-Schafer [95] reported prolongation of life by the use of 60 to 120 mg daily of thiouracil in patients whose heart failure had not responded to the usual therapy In seven to ten days there was a reduction in basal oxygen consumption a fall in venous pressure an augmentation of cardiac output and increased exercise tolerance

Radioactive Iodine (I^{131})

Blumgart and associates[88] *and Jaffe et al* [89] employed radioactive iodine (I^{131}) in euthyroid patients with heart failure for the purpose of lowering their metabolism and the work imposed on the heart [88] Blumgart et al [89] presented a summary of the results in the treatment with radioactive I^{131} of 1070 euthyroid patients with congestive heart failure or angina pectoris 87 from their own series and 983 reported by questionnaire from 49 other clinics Three hundred and fifty of the total represented cases of heart failure Treatment was confined essentially to patients who were incapacitated or unable to work despite the use of all available medical measures Three weekly doses of 20 millicuries of I^{131} or less (10 to 20 mc) are given to euthyroid patients Transitory thyroiditis and hypermetabolism may develop in the second and third week of treatment in about one third of the patients After the third dose additional doses are given at intervals of one to two months if necessary until myxedema appears Eight weeks to six months are required before the desired degree of hypothyroidism is produced Diminution of dyspnea and orthopnea usually occur at the time of onset of clinical hypothyroidism Thereafter a daily dose of desiccated thyroid (6–12 mg) is administered the dose being adjusted to obtain the lowest tolerable basal metabolic rate necessary to obtain relief of the heart failure without undue discomfort from myxedema As a rule a basal metabolic rate between −20 and −25 was satisfactory and a daily dose of 6 to 30 mg of thyroid extract Occasionally regeneration of thyroid tissue caused an exacerbation of symptoms and ne-

cessitated withdrawal of thyroid with subsequent retreatment with I^{131} The clinical results were quite favorable, about 60 per cent showing worthwhile results, of these about 20 to 25 per cent were considered excellent and 35 to 40 per cent good The remainder failed to show improvement The results in the treatment of heart failure were not as striking as in the treatment of angina pectoris (p 483)

Similar favorable results in 78 euthyroid patients with advanced heart failure were reported by Jaffe et al [185] who administered 6 millicuries of I^{131} orally each week until the patient had received 30 millicuries of radioiodine A second or third course was sometimes necessary They reported excellent results in 53 per cent, good results in 28 per cent and no improvement in 19 per cent

Although these results appear promising, the induction of myxedema in euthyroid patients cannot be regarded as a routine form of treatment even in patients with severe congestive heart failure *The procedure is unphysiologic* and adds another disease requiring continued therapy In many instances there is *uncertainty as to whether the improvement is* due to the radioactive iodine, to other measures simultaneously employed (e g better control of rest, *digitalization, restriction of* sodium intake) or to the natural variations in the disease Nevertheless, the administration of radioiodine to induce myxedema should be undertaken when severe recurrent pulmonary edema or chronic severe congestive heart failure does not yield to any other available form of therapy after prolonged and meticulous *trial In my experience the radioiodine treat*ment of congestive heart failure has not afforded impressive or consistent therapeutic results

EMERGENCY TREATMENT OF ACUTE LEFT VENTRICULAR FAILURE (CARDIAC ASTHMA PULMONARY EDEMA)

An effort should be made to determine the underlying cause and precipitating factors as these may modify management Thus if pulmonary edema is associated with acute coronary occlusion and shock, phlebotomy is rarely if ever part of the treatment On the other hand, the indication for phlebotomy may be especially strong if the attack is precipitated by excessive intravenous infusions *or transfusion* Rapid intravenous digitalization with ouabain may be the prime therapeutic agent if acute left ventricular failure results from the sudden onset of atrial fibrillation with a very rapid ventricular rate When acute left ventricular failure is *precipi*tated by some other paroxysmal tachycardia the former may be most effectively controlled by checking the paroxysm with *carotid sinus* pressure digitalization, quinidine or other agents as discussed in Chapter 14 In the presence *of pneumonia or other serious infec*tion prompt and adequate antibiotic therapy may be essential to the control of pulmonary edema

In general, morphine is administered in doses of 10 to 20 mg (1/6 to 1/3 grain) subcutaneously intramuscularly or occasionally intravenously, according to the urgency of the situation Atropine may be combined in doses of 0 4 to 0 6 mg (1/150 to 1/100 grain) if tachycardia is not a prominent feature Aminophylline (0 25 to 0 5 gm) should be infused intravenously at a slow rate If excessive respiratory *depression results from morphine* or other opiates, give 15 mg Nalline subcutaneously and repeat at 20 minute intervals *until patient is aroused The patient should be* propped up high in bed or be permitted to sit with support while his feet hang down from *the side of the bed or the head of the bed is* raised by blocks Oxygen therapy should be given promptly preferably under slight posi*tive pressure (4 to 8 cm of water)*[4] *if shock is* absent Helium-oxygen mixtures are preferred if available [5] The oxygen under pre*sure increases intra alveolar pressure* and prevents transudation of fluid from the alveolar capillaries Tourniquets should be applied serially *to the four extremities* with periods of release If there is no contraindication, the patient should be rapidly digitalized intravenously *if the emergency demands it* *Ouabain or Cedilanid* is administered intravenously as described previously (p 263) Because *respiratory obstruction in acute pul*monary edema may be intensified by the mechanical interference of foam due to edema fluid *inhalation of antifoaming agents* has been utilized[2,9] Usually 50 per cent ethyl alcohol is employed as the antifoaming agent but *the synthetic 2-ethylhexanol is* said to be much more rapid acting [70] The nebulized antifoaming drugs are administered by mask, by *bubbling oxygen with a positive* pressure apparatus through the drugs in a humidifier *Hexamethonium*, which reduces

the peripheral arteriolar resistance may be worthy of trial in cases of pulmonary edema in patients with severe hypertension but even when the heart failure is not associated with hypertension [351, 73, 104] If these measures are ineffective and there is evidence of an increased venous pressure and a high blood volume a phlebotomy should be performed (p 289) Other measures will be determined by the underlying disease and the precipitating factor

In cases of cardiac asthma of moderate severity or of mild pulmonary edema not all of these measures are necessary Assumption of the upright position and the injection of morphine may suffice Not infrequently the patient spontaneously sits up or jumps up out of bed to stand or sit near a window and is better before the physician arrives Nitroglycerin 0 6 to 1 2 mg (1/100 to 1/50 grain) administered sublingually afforded prompt relief of nocturnal dyspnea in 10 patients with left ventricular failure without angina pectoris according to Johnson et al [197] Only if these measures are inadequate should the physician successively add the application of tourniquets oxygen therapy the administration of aminophylline and digitalis etc

Prophylactic measures to prevent recurrence may include sleeping with the head elevated (cardiac bed) careful sodium restriction the use of diuretics and digitalization avoidance of excessive and sudden physical exertion the control of cough and the use of anticoagulants if the attack is precipitated by an embolism Pulmonary edema may be avoided in cardiac or elderly subjects if caution is used in the administration of intravenous infusions and the use of sedimented ("packed") erythrocytes instead of whole blood for transfusions [11] The patient's head and shoulders should be raised during the infusion or transfusion Recurrent pulmonary edema in patients with mitral stenosis is usually an indication for mitral commissurotomy For treatment of shock with pulmonary edema in acute myocardial infarction see page 566

TREATMENT OF INTRACTABLE HEART FAILURE [309, 268, [illegible], 306]

Despite all the therapeutic measures detailed in this chapter patients sometimes do not respond or cease to respond and the manifestations of heart failure persist or progress This state of unresponsiveness is often termed refractory or intractable heart failure When confronted with what is apparently intractable heart failure the physician should critically and systematically review the case for both a possibility of error in diagnosis and possible deficiencies or complications of treatment

Review of Accuracy of Diagnosis

The diagnosis of heart failure is based essentially on two manifestations dyspnea and edema and their variants Therefore it is necessary to exclude the numerous diseases which can produce dyspnea or other evidences of abnormal water retention Various bronchopulmonary diseases metastatic carcinomatosis various forms of anemia especially that due to chronic gastrointestinal bleeding hepatic and renal disease are among the more common conditions which produce clinical features simulating heart failure Definite evidence of underlying cardiac disease cardiac enlargement prolongation of the circulation time and elevation of the venous pressure in the upper and lower extremities are important features supporting a clinical diagnosis of heart failure

Remediable Factors Responsible for Persistent Heart Failure

A search should be made for possible factors responsible for precipitating heart failure or for rendering it refractory to treatment especially since some of them may be eliminated or ameliorated Among these are (1) hyperthyroidism (2) anemia (3) beriberi (4) arteriovenous fistula (5) arrhythmia with tachycardia (6) rheumatic fever (7) bacterial endocarditis (8) pulmonary embolism (9) hypertension (10) hepatic cirrhosis In particular in my experience masked hyperthyroidism and constrictive pericarditis are overlooked and are responsible for persistent symptoms of heart failure Both conditions are curable with dramatic improvement of the heart failure On the other hand if overlooked they prevent alleviation of heart failure despite the most vigorous exercise of all conventional therapeutic agents Not infrequently persistent heart failure is due to recurrent pulmonary emboli and relief of the heart failure may be obtained if embolization is prevented by the use of anticoagulants or by ligation of the veins of the lower extremity or of the inferior vena cava Similarly anemia thiamine deficiency and in

fection, especially of the pulmonary or urinary tract, should be sought and corrected, if possible When persistent heart failure is directly or indirectly due to mitral stenosis, coarctation of the aorta patent ductus arteriosus, other surgically correctible congenital cardiovascular anomalies or pheochromocytoma, the feasibility of operative correction should be considered

Adequacy of Therapy of Heart Failure

Ordinarily heart failure may be alleviated with moderate restriction in activity, digitalization and moderate reduction in sodium intake Many imperfections in treatment will not necessarily prevent a favorable therapeutic result But in cases of intractable heart failure it is essential that every therapeutic measure be carried out with the most meticulous perfection in order to succeed The limitation of the patient s activity or the completeness of his bed rest may be inadequate for the severity of the heart failure When heart failure appears intractable, it is particularly important that sodium restriction should be strict, i e not more than 200 to 500 mg sodium daily and that adherence to the diet be carefully checked The occasional response of purported cases of intractable heart failure after a few days of hospitalization is usually due to stricter bed rest or better control of low sodium intake Sometimes rigid restriction of sodium intake is best effected by the use of the Kempner rice-fruit diet or by combining a low sodium diet with cationic exchange resins

Intractable heart failure is rarely due to inadequate digitalization, not uncommonly, however to overdigitalization especially in patients with heart failure and sinus rhythm This should be checked by careful review of dosage clinical features and electrocardiograms

Occasionally apparently intractable heart failure is controlled by more frequent administration of mercurial diuretics or by combining the mercurials with adjuvants such as ammonium chloride aminophylline or Diamox The use of opiates or barbiturates may interfere with mercurial diuresis Large pleural effusions or ascites should be tapped Sometimes too much emphasis is placed on one or another therapeutic agent to obtain relief of intractable heart failure with neglect of other therapy Success often depends on the simultaneous attention to all possible measures Thus increasing frequency of injection of mercurials may succeed only if sodium intake is adequately restricted or only after adequate sodium restriction and bed rest, or only after these measures plus cationic resins, ammonium chloride, aminophylline and Diamox are all utilized in combination

Intractable heart failure is often noted at the same time that there are abnormalities in the blood electrolyte pattern (p 275) Because of this ammonium chloride may be administered when there is evidence of hypochloremic alkalosis or hypertonic sodium chloride when there is severe hyponatremia Occasionally these measures result in clinical improvement But most often the electrolyte disturbances are the result of the same disturbances that produced the intractable heart failure rather than the cause One should be careful not to exaggerate the importance of chemical changes in the blood presumed to be due to too vigorous therapy when the error lies in inadequate utilization of available therapeutic measures overlooked infection improper antibiotic overdigitalization or uncontrolled pulmonary embolization The use of mercurial diuretics and the increased understanding of the application and effectiveness of *very low* sodium diets are two of the most important advances in the therapy of heart failure It would represent a step backward to surrender the advantages of these measures because of an exaggerated emphasis on occasional dangers of sodium "depletion" or hyponatremia Finally, it must be recognized that sooner or later heart failure *becomes intractable because of the advanced* and irreversible nature of the cardiac disability This admission can be made only after every effort has been made to carry out all available therapeutic measures as indicated

Chapter 12

ACUTE CIRCULATORY FAILURE SHOCK, SYNCOPE AND SUDDEN DEATH

Acute and Chronic Circulatory Failure

Circulatory failure has been defined as the inability of the circulation to maintain an adequate minute volume blood flow to supply the needs of the tissues In the preceding chapters I have discussed chronic circulatory failure (congestive heart failure) in which the deficiency in cardiac output is gradual in development and moderate in degree Compensation is effected at first by cardiac enlargement and later by a variety of adjustments which tend to restore an adequate cardiac output Many of the manifestations of chronic circulatory (congestive heart) failure are due, not to the inadequate output per se, but to the consequent pathologic physiologic adjustments such as sodium and water retention and increased circulating blood volume

This chapter is concerned with the more acute forms of circulatory failure in which the deficiency in cardiac output occurs so rapidly and is of such intense degree that it is impossible to restore a relatively normal output by the above compensations Instead compensatory mechanisms are brought into play which redistribute the available low output in such a manner as to maintain an almost normal blood flow to vital organs at the expense of less important visceral and peripheral tissues In large measure the different clinical pictures associated with acute and chronic circulatory failure are due to the differences in compensatory processes as well as to differences in the severity and speed of development of an inadequate cardiac output

Shock, syncope and sudden death are forms of acute circulatory failure which differ in speed of onset of the circulatory failure and in severity and reversibility Sudden death occurs when the fall in cardiac output is so rapid and severe that vital medullary centers receive insufficient blood for survival Syncope denotes a very acute circulatory failure in which the available compensatory mechanisms cannot maintain an adequate blood flow to the brain, but as a rule the cerebral ischemia is transient and reversible In shock, the clinical picture develops rapidly but not as suddenly as in syncope Several hours usually elapse before the dynamic processes responsible for shock evolve the distinctive clinical phenomena Syncope and sudden death may also occur independently of acute circulatory failure

Shock syncope and sudden death are closely related in that one may merge into the other Transient attacks of syncope may be followed by one which is fatal Shock may occur with or without syncope

SHOCK

DEFINITION OF SHOCK

The term *shock* was originally applied to a clinical syndrome, is still recognized and diagnosed on the basis of clinical phenomena and should be defined in terms of these phenomena *Shock is a form of acute circulatory failure characterized by the rapid development of mental torpor and physical weakness, coldness of the extremities cold moist skin, rapid and weak pulse and a fall in arterial blood pressure* Unfortunately these criteria do not permit universal agreement as to the diagnosis in individual cases Generally, the diagnosis of shock is acceptable if there is hypotension below 80 mm Hg in association with the above clinical features Shock varies considerably with respect to severity and reversibility Hence it is often difficult to evaluate therapeutic agents

Shock is said to be *reversible* in the early stages when circulatory function may be restored by appropriate therapy Later there

develops a stage of *irreversible shock* which progresses to fatal insufficiency despite all therapeutic measures

Shock is sometimes used synonymously with peripheral circulatory insufficiency However the clinical syndrome and physiologic disturbances characterized as shock may be of cardiac or peripheral origin Furthermore since the circulation is an integral unit it is misleading to refer to a generalized circulatory insufficiency as peripheral

CLASSIFICATION OF SHOCK

Shock may be classified according to physiologic disturbances which result in a diminished volume flow of blood (cardiac output) These include (1) acute disturbances in (a) cardiac filling or (b) cardiac emptying which thereby sharply reduce the cardiac output, or (2) acute diminution in venous return due to a loss of blood plasma or intravascular water or to a pooling of blood in the small blood vessels

Shock is also classified according to the causative clinical conditions such as hemorrhagic shock traumatic shock burn shock etc These are incorporated in the following combined physiologic and clinical classification

Acute Circulatory Failure

- A Shock
- B Syncope (p 312)
- C Sudden death (p 316)

Shock

I Acute Deficiency in Venous Return
- A Deficient blood volume due to loss of blood or plasma
  1. Hemorrhagic
  2. Traumatic
  3. Surgical or postoperative
  4. Burn shock
- B Deficient blood volume due to dehydration and sodium depletion
  1. Vomiting and diarrhea (acute intestinal obstruction cholera acute diarrheas of infancy gastrointestinal external fistulae)
  2. Diabetic acidosis
  3. Addison s disease
  4. Heat exhaustion and syncope
- C Pooling of blood in small vessels (neurogenic? vasogenic? toxic? reflex? infectious?)
  1. Abdominal and testicular trauma
  2. Perforation of a hollow viscus
  3. Spinal anesthesia
  4. Acute pancreatic necrosis?
  5. Acute diffuse peritonitis?
  6. Acute febrile infections?
  7. Toxic forms of shock?

II Acute Deficiency in Cardiac Filling
- A Mechanical hindrance
  1. Sudden hemopericardium
  2. Acute pericardial effusions
- B Severe tachycardias with abbreviated diastole

III Acute Deficiency in Cardiac Emptying
- A Myocardial injury
  1. Acute myocardial infarction
  2. Rupture of valve cusp chorda papillary muscle or of septum
  3. Diphtheritic or rheumatic myocarditis (?)
- B Mechanical hindrance
  1. Massive pulmonary embolism
  2. Ball valve thrombus or tumor of left atrium
  3. Extreme mitral stenosis

PATHOLOGIC PHYSIOLOGY

Fundamental Mechanism[26, 158, 21, 27, 64, 103]

Despite the variety of clinical conditions and physiologic disturbances which may lead to shock there is a fundamental mechanism common to all which determines the clinical picture This common denominator is a rapid and severe *reduction in cardiac output with consequent tissue anoxia* Secondary (compensatory?) consequences of the reduction in cardiac output also contribute to the production of clinical manifestations

Shock is a dynamic process and its physiologic abnormalities may be considered in three stages (1) initial disturbances (2) compensatory mechanisms (3) stage of irreversible shock

1 *Initial Disturbances.* Like chronic circulatory failure acute circulatory failure begins with an inability of the heart to maintain an adequate output of blood[105, 3, 174] This may be caused by a reduction in blood volume and consequent diminution in venous return to the heart or it may be due to some cardiac or extracardiac disease which prevents the heart from filling or emptying properly

The low cardiac output may be denoted clinically by the mental and physical weakness low metabolism and occasional sub-

normal temperature The weakness of the pulse *and a low pulse pressure may be evi* dence of an extremely small stroke output The tachycardia, usually present is a well known cardiac compensation for a diminished stroke volume Actual measurements have disclosed early and sharp reduction of cardiac output in experimental shock [105, 167] By means of intracardiac catheterization and the use of the Fick principle Cournand and his associates[32] determined the cardiac output in clinical cases of shock due to skeletal trauma hemorrhage or burns Regardless of the type of injury they found the essential circulatory abnormality in these cases of shock to be a reduction in the cardiac output averaging about 35 *per cent* The right atrial and systemic venous pressure are diminished The circulation time is prolonged as determined with the aid of radioactive red cells or dyes in *animals with experimental shock* [203, 166] *The* delay appears to be in the systemic vessels since the pulmonary circulation time was found to be normal

2 Compensatory Mechanisms The sudden and severe fall in cardiac output is a threat to all tissues but especially to the brain which is most sensitive to anoxia and to the heart which is also vital for survival It is essential that the reduced volume flow available be redistributed in favor of the brain and heart and at the expense of the peripheral tissues and splanchnic viscera [6, 4] Moreover an adequate blood pressure must be maintained in order to perfuse these vital organs Both objectives can be and are accomplished by widespread vasoconstriction Because of the relatively *poor vasomotor innervation of the cerebral* and coronary arteries, their blood flow is relatively little affected by the generalized vasoconstrictor mechanism On the other hand vasoconstriction in the skin and splanchnic vessels so increases the peripheral resistance that blood pressure is maintained at much higher levels than would otherwise be possible with the diminished cardiac output

In contrast with chronic circulatory failure (congestive heart failure) vasoconstriction and redistribution of blood flow are the major compensations for shock, a compensatory increase in *blood volume may occur but is of* negligible significance In chronic circulatory failure, there is adequate time to increase the blood volume, which tends to restore a relatively normal output in the early stages, *vasoconstriction also occurs but is of* secondary importance

The occurrence of widespread vasoconstriction and redistribution of blood in shock has been demonstrated by many clinical and experimental observations [11, 14]

Perhaps the most striking evidence of intense vasoconstriction is found in the skin, which is extremely cold and moist, especially in the distal parts of the circulation such as the extremities and tips of the nose Baldes and associates[10] found that when shock was induced in dogs by intestinal manipulation there was as much as 75 per cent reduction in blood flow through the femoral artery even though the blood pressure was maintained at normal levels Similar evidence of disproportionate vasoconstriction may be found in the experiments of Erlanger, Gesell and Gasser [■] *who observed a 60 per cent reduction in the* blood flow through the salivary gland, following only a 10 per cent reduction in circulating blood volume without change in arterial pressure *In clinical cases of surgical shock Free*man, Shaw and Snyder [75] with the aid of the venous occlusion plethysmograph, observed a striking diminution in blood flow through the hand and a loss of the normal ability to increase this flow by warming or by applying and releasing a tourniquet The fact that the blood flow (cardiac output) in experimental and clinical shock generally declines before the blood pressure falls, also indicates the early development of vasoconstriction [105, 91, 161]

Of special interest are the findings that in the early phase of shock there is a decline in *renal blood flow which is even greater* than the decline in cardiac output [113, 161, 198] Thus while the total blood flow decreases to about half of normal the renal blood flow, which is normally 20 to 25 per cent of the total is reduced to one tenth or less of its usual amount [113]

The existence and significance of renal shunts[197] through the renal medulla in cases of shock is undetermined Apparently, in acute as in chronic circulatory failure, the kidneys play an important role in the defense of the organism either in restoration of cardiac output by retention of sodium and water and thereby increasing the blood volume and venous return, or by a vasoconstrictive redistribution of an inadequate blood flow and maintenance of blood pressure

The mechanisms by which vasoconstriction redistribution of blood and maintenance of blood pressure are effected are probably multiple The role of the adrenal medulla and sympathetic nervous system is best known That sympathetic vasoconstriction is important in producing the shock syndrome is denoted by the cold sweat in human cases and by the difficulty in producing experimental shock after bilateral sympathectomy [7] There is also evidence that reflexes by way of the carotid sinus and vasomotor center adrenal cortical hormones [77] and renin like or other pressor substances released from the kidney in response to ischemia[33, 184] participate in the compensations for acute circulatory failure

At the same time that these vasoconstrictive phenomena are occurring in various organs and tissues during the compensatory stage of shock the blood pressure may decline but is still adequate for cerebral and coronary blood flow There may be mental apathy but consciousness and coherence are usual There is no clinical or electrocardiographic evidence of significant cardiac damage or of an inability of the heart to handle the venous return [211]

3 *Stage of Irreversible Shock.* Prolonged severe shock eventually leads to failure of these compensatory mechanisms, with consequent progressive decline in cardiac output and blood pressure profound tissue anoxia involving also the heart and brain and death During the uncompensated or irreversible stage of shock restoration of blood volume and other therapeutic measures which are usually effective in the early stages are incapable of altering this baneful series of events

During the stage of irreversible shock the continued fall in cardiac output and in blood pressure occurs even when there is no significant further reduction in blood volume The circulation time becomes greatly prolonged These findings suggest that the decline in cardiac output in this stage is due to peripheral stasis and the inability to build an adequate blood pressure is due both to the failing output and the failure to maintain compensatory vasoconstriction In other words irreversible shock is associated with a reduction in peripheral resistance and a pooling of blood in small vessels

These concepts are supported by direct observations of capillaries in various animals with induced shock In the compensated stage there is accentuated vasoconstrictor activity of metarterioles and precapillary sphincters and hyperreactivity to small doses of epinephrine In the irreversible stage there is a diminution in vasomotor activity with dilatation of arterioles and venules diminution or absence of response to epinephrine capillary stagnation and eventual cessation of blood flow [270, 31, 115] Postmortem observations have disclosed generalized capillary dilatation and stasis and packing with erythrocytes Studies of blood volume in experimental shock with radioactive isotopes disclosed evidence of widespread 'trapping' of red cells within the minute vessels of all the organs of the body [80] Thus in the irreversible stage of shock pooling of blood in atonic small vessels intensifies the previous deficiency in venous return and cardiac output and nullifies the compensatory mechanisms which maintained a sufficient blood pressure and blood flow to vital organs However these secondary and terminal occurrences should not be confused with the initiating causes of shock

The actual cause of irreversibility of shock is uncertain Metabolic or toxic changes induced in the organs which suffered from prolonged and intense vasoconstrictive anoxia during the compensated period of shock are the most probable factors inducing irreversible shock The importance of compensatory vasoconstriction in causing irreversible shock is supported by the observation that the occurrence of irreversible hemorrhagic shock in experimental animals was delayed and its incidence diminished when dibenamine a sympatholytic drug was administered twenty hours before the shock producing venesection [214] The mortality from hemorrhagic and other forms of shock in rats was largely prevented by pretreatment with dibenamine [8] The vascular atony and capillary stasis and trapping of blood may be due to the direct or indirect effects of prolonged vasoconstriction and tissue anoxia

Of the organs suffering from vasoconstriction the *liver* is most sensitive to anoxia perhaps because of the relatively low normal oxygen content in the portal vein its chief source of supply There is considerable evidence of hepatic dysfunction in shock as denoted by the rise in blood amino nitrogen[30, 178] and other chemical changes (p 309) Further evidence of the role of liver damage in irreversible shock is seen in the observation that

irreversibility of hemorrhagic shock in dogs can be prevented by via perfusion of the liver (by way of the splenic vein) with normal donor's blood.[69, 205] Similar arterial transfusion into the jugular vein of the shocked animals was ineffective. Ligation of the dog's inferior vena cava above the liver produced prompt shock, which could not be reversed by infusing any amount of whole blood or saline solution.[64] Shorr and his associates[184] reported the finding of a humoral substance ("vasodepressor material"—VDM identified as the iron-containing protein ferritin) elaborated essentially by skeletal muscles and liver after prolonged shock and responsible for the atony and stasis found in small blood vessels in the irreversible stage. On the other hand, a direct relation of ferritin (VDM) to shock is improbable since it was incapable of inducing shock in dogs when injected intravenously in large doses, even after the liver and kidneys were removed.[67, 182]

The *kidney* has been mentioned as suffering from intense vasoconstriction and reduction in blood flow during the compensated stage of shock. This may lead to organic renal changes, especially in the tubules, if shock is severe and prolonged (lower nephron nephrosis[199, 200]). Oliguria or anuria, urine of low specific gravity, low urea clearance and uremia may result. Such renal failure may develop as a result of prolonged anoxemia and organic changes even after normal circulatory function has been reestablished, as in the so-called crush syndrome (p. 953). Renal failure may contribute to the acidosis of shock and may itself be responsible for death. But it is unlikely that renal anoxia is responsible for the irreversible stage of shock.

Anoxia of the *skeletal muscles* during prolonged shock gives rise to metabolic disturbances which contribute to the alterations in blood chemical findings (p. 309).[43] But the possible role of these disturbances in irreversible shock is uncertain.

The *heart* itself, which is fairly well supplied with blood during the compensated stage, may suffer if shock is severe and prolonged.[211] Depression in myocardial function may thereby contribute to the circulatory debacle that occurs during irreversible shock. Wiggers and Werle[213] showed that the capacity of the ventricles to respond to progressive increments of filling (venous) pressure was reduced in animals with hemorrhagic shock. Kohlstaedt and Page[118] observed a stage of cardiac constriction followed by one of cardiac dilatation corresponding to similar peripheral vascular changes in progressive shock. Prinzmetal and Bergman[164] observed a maximal increase in the number of open capillaries in the hearts of rats with burn shock and concluded that the heart in shock suffers from decreased coronary flow, capillary atony with retention of metabolites and myocardial dehydration. Other studies indicate that there is myocardial ischemia from diminished coronary flow in experimental hemorrhagic shock and that there are consequent metabolic changes in heart muscle, such as a destruction of cocarboxylase.[43] A sharp reduction in the normally high myocardial extraction coefficient of pyruvate has been noted, as well as relative myocardial oxygen deficiency.[69] Opdyke and Foreman[154] reported experimental evidence that although the coronary blood flow may be reduced in shock, it is adequate in terms of the diminished work of the heart. On the other hand, Sarnoff and associates[177] noted myocardial failure with a rise in left and right atrial pressures as a complicating factor in experimental hemorrhagic shock. These observations indicated that deficient coronary blood flow contributed to the myocardial failure. In cases of clinical shock, e.g., after acute hemorrhage or massive pulmonary embolism, we have observed myocardial necrosis or infarction without coronary occlusion, due undoubtedly to functional coronary insufficiency.[79] Despite these evidences of late myocardial damage in severe shock, it is probable that they are the consequences and not the cause of irreversible shock.

The *cerebral blood flow* is diminished during shock, but cerebral metabolism may be normal or diminished and oxygen extraction increased or reduced.[63, 6a] Apparently, cerebral metabolism may be maintained at normal levels in some cases despite diminished cerebral blood flow.

ETIOLOGY AND PATHOGENESIS

Bacterial Infection

Various studies in experimental animals have implicated intestinal bacteria as responsible agents in irreversible shock.[61] When shock was produced by bleeding, dogs to which antibiotics had been first administered experienced a lower mortality rate and greater tolerance to the hypotension than dogs which

had not received antibiotics Furthermore in the dogs with antibiotics rapid recovery could be effected by restoration of the full volume of blood when shock was irreversible in the control animals A lethal factor was obtained from the livers of dogs in irreversible hemorrhagic shock and this factor was found to depend on bacterial action during the state of shock[170] On the other hand Nelson and Noyes[147] found an almost identical incidence of positive blood cultures of Clostridium perfringens and Corynebacterium in control dogs and dogs in terminal hemorrhagic shock But whether or not such bacteria contribute to irreversible shock in the dog the applicability of such a mechanism to the human is improbable partly because of the significant difference in bacterial flora in the dog and the human

Acute Deficiency in Venous Return Caused by Loss of Blood or Plasma Volume[3, 26, 212, 44]

Under this heading are included cases of shock due to hemorrhage trauma burns surgery etc in which the initiating cause is a reduction in circulating blood volume Harrison[86] refers to this group as hematogenic shock and Fishberg[62] terms it oligemic shock The reduction in circulating blood volume results in a diminution in the venous return and consequently in a decline in cardiac output Diminished venous return is denoted in clinical shock by the collapsed superficial veins and by the finding of very low atrial pressures by cardiac catheterization[3] A progressive increase in the circulation time[203] indicates that slowing of blood flow later accentuates the decline in venous return

The classic studies of Robertson and Bock[170] and of Keith[111] during World War I disclosed striking reductions in circulating blood volume in cases of traumatic or wound shock and a definite relationship between the reduction in blood volume and the severity of shock Numerous other experimental and clinical studies have demonstrated the close causal relationship between reduction in blood volume and the development of hemorrhagic traumatic and burn shock Studies of traumatic shock in dogs revealed that the clinical picture of shock appeared when there was at least a 30 per cent reduction in blood volume and in dogs that succumbed the reduction was 40 per cent or more[87] In clinical studies of traumatic shock similar pronounced declines in circulating blood volume (30 to 40 per cent below normal) were discovered with the aid of the blue dye T 1824[3, 131] Practically this denotes that clinical shock follows the rapid loss of about 1 5 to 2 0 liters of blood Similar reductions in blood volume occur in burn shock[119] The latter usually develops when more than 10 per cent of the cutaneous surface is involved

Theories of Reduction in Blood Volume

Local Fluid Loss The cause of the reduction in blood volume is usually clear when there is massive external bleeding In surgical or postoperative shock the amount of blood loss during operation is much greater than was formerly recognized Preoperative and postoperative vomiting or bleeding and loss of fluids from excessive perspiration are factors contributing to the reduction in blood volume

In recent years it has become increasingly manifest that gross reductions in blood volume in cases of wound skeletal and burn shock may be due entirely or almost entirely to the extravasation of blood or plasma out of the blood stream and into the injured area When shock was induced in animals by trauma to a hind leg comparative weights of the injured and normal legs disclosed that the loss of blood and plasma into the injured leg was sufficiently large to account for the reduction in blood volume and occurrence of shock[13] Similarly shock induced experimentally by intestinal manipulation or by burns could be explained by the local loss of fluid in the burned or damaged tissues[77, 81] These findings have been confirmed by Nickerson[149] and by Ashworth et al[7] who demonstrated quantitatively that the fluid loss was equal to the observed reduction in circulating blood volume Of interest also in this connection are the observations of Duncan and Blalock[40] that shock does not develop if local fluid loss after trauma is prevented e g by application of a cast In certain forms of experimental burn shock there is a diminished circulating blood volume but little or no evidence of fluid loss since capillary atony and visceral congestion are prominent the shock has been attributed to capillary stasis due to a toxic humoral factor and consequent reduction in venous return[144]

Toxic Factors The production of circulatory failure with a fall in blood pressure and reduction in blood volume following the injection of histamine[31] suggested that toxic

substances liberated by injured tissues might be responsible for shock. Shock has been produced by a variety of extracts of normal and traumatized tissues but the results are not consistent and the type of shock induced differs in fundamental respects from traumatic shock.[11, 138, 113] Similarly cross circulation experiments in which the production of shock was attempted by transfusion of blood from shocked to normal dogs have usually been unsuccessful or insufficiently controlled.[13, 83] Although infection may be a complicating factor in some cases of traumatic shock,[61] it is neither a usual nor a fundamental cause of the shock syndrome.

Several variants of the toxic theory of shock have been recently proposed. It has been shown that, at least in experimental traumatic shock, bacterial toxins may be important, especially the toxins of clostridia.[166] The reported appearance of a vasodepressor material from shocked liver and skeletal muscle has been mentioned.[164] Profound metabolic changes with alteration of the chemical pattern of the blood have been reported,[43] but these are secondary factors which may enhance the progress of shock and lead to irreversibility, but do not initiate the disorder. Retention of potassium with hyperpotassemia may occasionally be a contributing factor in causing death,[16] but is not of primary importance in the etiology of shock. The *adrenal cortex* participates in the metabolic reactions to shock, but is not the cause of traumatic shock or of its irreversibility.[49, 96]

Nervous factors have been invoked as the possible cause of shock, but the weight of evidence is strongly opposed to the concept that traumatic shock of the type under discussion is induced by nervous reflexes.[160] The occurrence of so-called primary or neurogenic shock is discussed below.

The theory of generalized capillary permeability with leakage of fluid from the circulation, as contrasted with local extravasation in the injured area, has been championed most vigorously by Moon.[138] This was based essentially on (1) pathologic findings in shock which represent terminal changes, (2) analogy with the findings in histamine shock which differs fundamentally from traumatic shock, and (3) an exaggerated emphasis upon hemoconcentration of blood, which has recently been shown to be absent except in shock due to burns or abdominal injuries with peritonitis.[31] On the other hand, there is adequate evidence that the reduction in blood volume can be explained by local fluid loss[13]; studies with radioactive sodium show a decrease in transcapillary exchange instead of the increase to be anticipated if capillary permeability were enhanced[79], and a study of radioactive proteins in hemorrhagic and tourniquet shock[67] and of radioactive dyes in burn shock[29] discloses no evidence of generalized capillary leakage. The theory of generalized capillary leakage no longer appears tenable.

Acute Deficiency in Blood Volume and Venous Return Due to Dehydration

In this etiologic type of shock, a deficient venous return and cardiac output are likewise due to a reduction in circulating blood volume, the latter is caused, not by a loss of blood or plasma, but by an excessive loss of fluid and electrolytes by way of the kidney, gastrointestinal tract or skin. This type of shock is sometimes termed "medical shock."[4] Because the loss of blood volume is due to or concomitant with a loss of sodium, the clinical picture of shock is complicated or overshadowed by the effects of loss of base (acidosis) and tissue dehydration.

In the intense *gastroenteritis* of infancy, in *cholera* and in *high intestinal obstruction* with vomiting, the excessive loss of fluid is obvious, while oral replacement is either impossible or grossly inadequate. With vomiting there is chiefly loss of chlorides with some sodium, and with diarrhea chiefly a loss of sodium. Since the extracellular water content is essentially a function of dissolved electrolytes, such loss of ions is associated with a reduction in circulating blood volume. Actual diminution of blood volume due to diarrheas of infancy has been noted.[35, 133]

In *diabetic acidosis*, there is an excessive loss of sodium through the kidneys, both as sodium chloride and in combination with ketone radicles.[7] This results in an excessive loss of fluids which are not replaced because of nausea or vomiting, and consequently in a reduction of blood volume and shock.[159]

In *Addison's disease*, deficiency of the sodium regulating factor of the adrenal cortex leads to excessive renal excretion of sodium, a corresponding loss of fluid and a reduction in circulating blood volume.[172] The fluid loss is often intensified by diarrhea and vomiting which occur during crises. The clinical picture

of shock in Addison's disease is complicated not only by dehydration but by disturbance in carbohydrate metabolism by retention of potassium and by fever and sensitivity to mild infections

Acute Deficiency in Venous Return Due to Pooling of Blood in Small Vessels

A deficiency in venous return and in cardiac output with a consequent clinical picture of shock can result from pooling or stagnation of blood in small vessels and without any external loss of blood or plasma Such pooling may result from direct impairment of vascular tone with consequent vasodilatation (vasogenic shock of Harrison[85]) or from reflex or neurogenic vasodilatation (neurogenic shock)

The former is represented by *histamine shock* and perhaps various types of chemical toxic or anaphylactic shock The neurogenic type of shock is represented by the almost immediate collapse which follows a bullet wound abdominal blow (solar plexus punch) testicular injury or perforation of a hollow viscus This type of shock is also classified as primary shock because of its early onset after trauma as compared with the secondary shock or wound shock which we have been discussing and which usually develops after several hours Syncope (p 312) is common in this neurogenic type of shock

This form of shock differs from the previous groups also in that a fall in arterial blood pressure (due to vasodilatation) precedes the decline in cardiac output This was observed particularly in the shock following experimental spinal anesthesia[19] According to the observations of Smith and collaborators[185] the relaxation involves the postarteriolar vessels i e the capillaries and small venules

There is uncertainty as to the mechanism of shock in such conditions as acute pancreatic necrosis large peripheral embolism acute diffuse peritonitis and acute infections[4, 98, 71] Direct or reflex vasodilatation due to toxic substances reflex vasodilatation due to neurogenic impulses and in some cases also local extravasation of fluid and dehydration may be concerned Gilbert and associates[81] found that the hypotension in 5 patients with shock due to infection was associated with a normal cardiac index and a low total peripheral resistance Norepinephrine administration was followed by a rise in arterial pressure without increase in cardiac output

Acute Deficiency in Cardiac Filling

This group comprises cases of shock due to the sudden development of inflammatory pericardial effusion or hemopericardium which compresses the heart and prevents its filling (cardiac tamponade) Occasionally the sudden development of an extreme tachycardia likewise prevents cardiac filling by abbreviating diastole In this group there is often a simultaneous initial pooling of blood proximal (upstream) to the right chambers of the heart i e in the systemic circulation Incomplete filling causes a sharp drop in cardiac output and shock or syncope[11]

A more detailed discussion of acute cardiac tamponade can be found on page 593 and of tachycardias on page 347

Acute Deficiency in Cardiac Emptying

There is a primary reduction in cardiac output in these cases either because of some mechanical obstruction (ball valve thrombus massive pulmonary embolism) or because of sudden impairment of cardiac function (acute myocardial infarction) This type of acute circulatory failure is sometimes termed cardiac shock or cardiogenic shock The clinical picture is essentially identical with that of shock due to an acute reduction in venous return The circulation time is usually prolonged but there are scanty data as to the blood volume

In cases of shock due to acute myocardial infarction there is a tendency to pooling of blood proximal (upstream) to the left cardiac chambers This often results in acute pulmonary congestion (left ventricular failure) in association with shock When acute myocardial infarction occurs in a previously insufficient heart there may be a combined picture of congestive heart failure and shock In contrast with the tendency to elevated blood volume in congestive heart failure the blood volume is usually somewhat reduced in cases of shock due to acute myocardial infarction[1]

The individual conditions responsible for this etiologic type of shock are discussed elsewhere under their respective headings

PATHOLOGY OF SHOCK

Since shock represents a dynamic progression of physiologic abnormalities the reported pathologic findings in experimental and clinical shock must be viewed as terminal changes in fatal cases

During abdominal operations on patients in shock the viscera and peritoneum are often found to be remarkably pale.[1] On the other hand Gasser Erlanger and Meek[78] observed great dilatation of capillaries and venules, packed with red blood cells, in various types of experimental shock. More recently Moon and Kennedy[140] and Moon[133] have especially emphasized the occurrence of diffuse capillary congestion, edema, effusions and petechial hemorrhages in the viscera following experimental and clinical shock.

Gastric and intestinal ulcers have been repeatedly observed in cases of shock due to histamine following adrenalectomy due to burns [?] and in patients who succumbed after major operative procedures or diseases associated with shock.[157] The pathologic findings in the latter group were interpreted as the result of intense vasoconstriction.[114]

There may be fat vacuoles in myocardial fibers in the central cells of the liver lobules and in the ascending loop of Henle in the kidney,[1,6] depletion of lipid in the adrenal cortex,[15] pulmonary fat embolism [228] and central necrosis of the liver.[48] Cerebral and coronary infarction may be precipitated by shock.

CLINICAL FEATURES OF SHOCK

General Appearance and Behavior[94]

The patient may be restless or he may lie quietly, apathetic and oblivious of his surroundings. Restlessness is common in the early stages of acute hemorrhage. Occasionally the patient in shock is able to drive himself home or to a physician's office or he walks into a hospital emergency room. Occasionally he is found wandering aimlessly about the scene of his injury.

More often the patient is extremely weak and incapable of any but the mildest physical exertion. Mental torpor corresponds with his physical lethargy. His responses are feeble and hesitant but usually coherent. Advancing shock is characterized by progressive physical and mental exhaustion bordering on coma. Sensation is dulled and responses become incoherent or absent.

The Skin

The skin is *pale and cold*. In very severe shock the pale skin is mottled bluish red (cutis marmorata) owing to irregular congestion and constriction of superficial blood vessels. The coldness and pallor of the skin are most pronounced in the hands, feet and tip of the nose. Occasionally, as in shock due to a ball valve thrombus or extreme mitral stenosis, I have seen intense cyanosis with foci of necrosis in these peripheral regions. The skin temperature may be low even when the patient is febrile.

A grayish cyanosis is frequent. *Excessive perspiration* renders the skin clammy as well as cold.

The *rectal temperature* may be subnormal due to a low rate of metabolism and loss of heat through perspiration.

The Pulse

A rapid weak pulse is characteristic. Terminally there may be a bradycardia. A rapid pulse usually appears before the decline in blood pressure and may be of diagnostic value.

The Respiration

This is variable according to the etiologic factor. Often it is deep and rapid due to increasing acidosis.

The Blood Pressure

Hypotension is characteristic of shock but the blood pressure may remain normal at the onset of shock when a significant decline in cardiac output has already occurred.[10] The compensatory vasoconstriction occasionally is so intense that the blood pressure is temporarily above normal.[116] However, a progressive decline in blood pressure is the rule. Usually the blood pressure is below 90 mm Hg and in very severe and in irreversible shock below 70. The *pulse pressure* is reduced.

The Heart

In the cases of shock due to a deficient venous return there is no overt evidence of cardiac impairment. Evidence of myocardial depression in advanced experimental shock has been discussed.

The Veins

The superficial veins are collapsed. The difficulty of inserting a needle is well known. The venous pressure is low (1 to 2 cm) and cardiac catheterization has disclosed that the right atrial pressure is likewise low.[22]

The Urine

The urinary output is diminished and in severe shock there may be complete anuria (p 953). Renal clearance studies show a depression of renal blood flow and of glomerular filtration. Despite a low urinary output the specific gravity may be low.

The Blood

A leukocytosis is common, especially in

hemorrhagic shock, but leukopenia may be present in severe shock.[21] A depression of circulating eosinophils is evidence of adrenocorticoid response to injury.[55, 56]

Hemoconcentration is usual in shock due to burns, to dehydration and in some cases of abdominal injuries. *Hemodilution* is observed in shock due to hemorrhage, skeletal trauma and crushing wounds.[22]

Hyperglycemia occurs early and is believed to result from a compensatory secretion of epinephrine.

Acidosis[21] is usual in well developed shock. It is due to an accumulation of lactic, phosphoric and pyruvic acids in the blood. Lactic and pyruvic acids increase because of excessive production in the skeletal muscles and because of impairment of liver function.[10] The increase in phosphates is due chiefly to impaired renal excretion. The accumulation of fixed acids releases bicarbonate which is eliminated as carbon dioxide through the respiratory tract. A diminution in alkaline reserve, denoted by a low carbon dioxide combining power, results from loss of sodium excreted in combination with the fixed acids. The pH of the blood may be significantly diminished but is usually relatively normal.

Urea and nonprotein nitrogen are elevated because of increased catabolism and deficient renal excretion.[3]

An *elevation of alpha amino nitrogen* results from increased catabolism and impaired deamination by the liver.[176] Elevation of arterial blood ammonia occurs in experimental oligemic shock and aggravates the clinical picture.[148]

The *arterial oxygen* is usually normal until preterminally. The *venous oxygen content* falls progressively.[167] The *arteriovenous oxygen difference* is increased. This is indicative of a prolonged circulation time which compensates for the low cardiac output by permitting a more complete oxygen extraction by the tissues.

Potassium may be increased because of increased protein catabolism, impaired renal excretion, or adrenal cortical deficiency.[165]

TREATMENT OF SHOCK

Prophylaxis

Many types of shock are easily preventable. In *surgical procedures* preoperative correction of dehydration and anemia, omission of drastic purgation, restoration of glycogen reserves in the liver, elimination of excessive sweating, careful hemostasis and minimal handling of tissues during the operation, expert administration of anesthesia and avoidance of long operations will minimize the incidence of postoperative shock. Traumatic shock may be avoided by prompt control of bleeding with the aid of pressure, ligature (or tourniquet, if necessary) and especially by rapid transportation to a hospital where more definitive measures can be carried out. Protection from cold and pain and the rapid splinting of injured parts are also valuable prophylactic measures.

Early Treatment

Successful treatment of shock must begin early, before the irreversible stage is reached. This means early diagnosis. The probability of shock should be gauged from the severity of trauma, the extent of a burn, outward evidences of bleeding, the nature of an operation or of other circumstances associated with the causative condition. If these circumstances suggest that shock is probable, treatment should be instituted before there are frank clinical evidences of shock.

Treatment

The *causative condition* should be corrected. This may mean the ligation of bleeding vessels, débridement of destroyed tissues, maintenance of a free respiratory airway, setting of fractures, closure of a perforated viscus, drainage of a pericardial effusion, removal of an atrial tumor, administration of adrenal cortical extract and sodium in Addison's disease, or of insulin in diabetic acidosis. In traumatic shock the patient should be kept supine or with the foot of the bed or stretcher elevated, except when there is a severe head injury, pulmonary edema or a chest wound associated with respiratory distress. Body warmth should be conserved but overheating should be avoided and the danger of burns should be remembered. Morphine or other narcotics or sedatives should be given only as needed to relieve pain or allay anxiety, overdosage being strictly avoided.

Transfusion of whole blood is the mainstay of treatment in shock due to hemorrhage or trauma.[19, 167] It has also been recommended in the treatment of burns.[84] Blood should be given *early* and in adequate amounts. The latter can be gauged by observation of the clinical response and determinations of the

blood count, hematocrit and blood volume In the presence of shock, recovery usually requires at least 1000 to 1500 cc of blood Arterial (radial or aortic) transfusion has been recommended in very severe cases of shock [116] Arterial transfusion[201, 31] may be preferable to intravenous transfusion in shock associated with cardiac arrest during complete heart failure surgery or mitral stenosis and possibly in cases of shock due to myocardial infarction *The arterial transfusion is designed* to raise aortic pressure and perfuse the coronary vessels without requiring cardiac activity On the other hand there is evidence that in hemorrhagic and traumatic shock transfusion of blood via an artery is no more effective than intravenous transfusion [2, 186] with respect to raising the arterial pressure and increasing the coronary blood flow The rate of infusion of blood may be more important than the route by which it is administered [127] Care should be taken to avoid the precipitation of pulmonary edema by too rapid or excessive transfusions (or infusions of plasma or saline) especially in elderly individuals and in those with known cardiac disease In cases of shock with extreme oliguria or anuria the parenteral administration of fluids must be given with particular caution because of the hazard of congestive heart failure Proper cross matching of blood with respect to type and Rh factor is essential

Plasma and other blood substitutes (plasma expanders) including human albumin, dextran polyvinyl pyrrolidone (PVP) and gelatins are relatively much less satisfactory in hemorrhagic traumatic or surgical shock Such blood substitutes are indicated in the early stages of burn shock in which there is relatively little loss of erythrocytes and the hematocrit is elevated [47] As a rough guide, 75 cc of plasma or plasma expanders are given in the first 24 hours for each per cent of body surface burned and somewhat less on the second day Thereafter the amount is gauged by the clinical condition *of the patient, and* by determinations of blood counts hematocrit specific gravity and chemical examinations of the blood [91, 5, 3] The danger of viral hepatitis is a serious disadvantage of plasma Fluid and electrolytes are given parenterally or orally to supplement the plasma Good results have been reported in the treatment of burn shock with very large amounts of sodium lactate [85]

Plasma Expanders [83, 94] This term refers substances of relatively high molecular weight which, when infused into the blood stream, remain long enough to augment the volume of circulating fluid by increasing the oncotic pressure These substances should be non toxic relatively inexpensive and not retained in the body indefinitely Three of the recently studied plasma expanders are dextran, polyvinyl pyrrolidone (PVP) and oxypoly gelatin (OPG) *The plasma expanders*, especially dextran, possess the advantage of a lower incidence of reactions than after blood or plasma, especially with regard to the occurrence of homologous serum jaundice

Dextran, which is a polydispersoid glycose polymer with a molecular weight conforming to that of albumin (about 100 000),[198, 106, 94] has recently been recommended and fairly widely used in Sweden as a plasma substitute for the prevention and treatment of surgical and other forms of shock Dextran is formed by the action of the bacteria Leuconostoc mesenteroides on sucrose It is not pyrogenic or toxic but some individuals experience allergic reactions [108] Prolongation of bleeding time and hemorrhagic tendencies may be observed among patients who have received large amounts of dextran according to Jaenike and Waterhouse [104] but no such bleeding tendency was noted by Artz et al [3] Most of it is removed slowly from the blood stream in four to seven days [18] Studies in dogs[105] of dextran labelled with radioactive carbon (C^{14}) disclosed rapid excretion of those fractions of dextran with a low molecular weight whereas the fractions of higher molecular weight were retained in *the body for longer periods* A high concentration of dextran (C^{14} activity) was found in the liver and lymph nodes and uniform distribution in other tissues Unlike most of the other plasma substitutes, dextran is normally metabolized [97] In cases of shock it is said to produce a prompt and lasting increase in blood pressure [200] It has been administered *intravenously as a 6 per cent dextran solution* in 0 9 per cent sodium chloride In surgical cases and combat casualties 500 to 1500 cc is usually employed [2, 70] Where there is marked loss of blood it should be replaced by blood alone But if there is only slight loss of blood dextran may be used to combat shock or a transfusion may be given followed by 500 cc of dextran Or dextran may be given first if there is a delay in obtaining appropriate blood

Studies in normotensive dogs[60] and in humans[5] indicate that dextran is a more effective plasma expander than either of the more recently introduced polymers PVP or OPG.[60] Other studies indicate that dextran produces striking increments in blood volume when administered to both normovolemic and oligemic (bled) human subjects, especially the latter.[90] The administration of 500 cc. of a 6 per cent solution of dextran was found to increase the blood volume by 960 to 2850 cc. (average 1880 cc.), the maximal increase occurring between one quarter hour and 6¼ hours after the infusion.[195]

Polyvinyl pyrrolidone (PVP)[167, 1, 120] This is a synthetic, water-soluble, hydrophilic polymer of heterogeneous molecular size with an average molecular weight between 35,000 and 40,000. It is administered intravenously in a 3.5 per cent solution in buffered physiologic saline which is virtually isotonic with normal plasma. Usually 500 to 1000 cc. is given to prevent or combat surgical shock. It was used successfully in Germany during and after World War II and has since been reported to be effective in obstetrical,[19] burn, traumatic[14] and hemorrhagic shock.[20] Its excretion resembles that of dextran, but its plasma levels are usually lower and it is somewhat less effective. Unlike dextran it is not metabolized, 40 to 50 per cent being stored and subsequently eliminated very slowly in a period of weeks or months.[22] The particles of largest molecular weight (above 120,000) are retained for years in the reticuloendothelial system.

Oxypolygelatin (OPG) is a gelatin polymer which may be administered intravenously in a 5 per cent solution in physiologic saline.[4, 83] Some batches of OPG are superior to PVP but in general OPG is less effective as a plasma expander than dextran.[89] There is a larger unaccounted loss of OPG following intravenous infusion than of either dextran or PVP.[89, 5]

Crystalloid solutions, especially an isotonic (0.85 per cent) solution of sodium chloride or other sodium-containing solutions, are given intravenously or subcutaneously until blood and plasma are obtained, to supplement plasma in burn shock, and in the treatment of shock due to dehydration. Potassium salts may be necessary in the dehydration diarrhea of infants.[82]

Vasoconstrictor (pressor, sympathomimetic) drugs[164, 74, 210, 137] have been more widely used in recent years in the treatment of all forms of shock, but are only of transient and secondary value when shock is due to blood loss. Their use is based on the premise that sympathetic vasoconstriction in shock is incomplete and that the dangerously low blood pressure of shock may be elevated by further vasoconstriction. The advantages of raising the blood pressure to maintain an adequate cerebral and coronary blood flow and glomerular filtration are regarded as outweighing the possible risks of further constriction of the peripheral and splanchnic vessels.

Norepinephrine (Levophed), Wyamine (mephentermine) sulfate, methoxamine (Vasoxyl), Neo-synephrine and metaraminol (Aramine) administered intravenously or intramuscularly have been used most frequently. They are discussed in connection with the treatment of shock in acute myocardial infarction (p. 562). Paredrine (10 to 20 mg. intramuscularly or 5 to 10 mg. intravenously) and Neo-synephrine (5 mg. subcutaneously) are useful in the shock which may follow spinal anesthesia.

Alkalis in the form of a 5 per cent solution of sodium bicarbonate or a $^1/_6$ molar lactate solution may be given to correct the acidosis associated with shock. About 60 cc. of the $^1/_6$ molar lactate per kilogram body weight increases the CO_2 combining power of the blood 25 to 35 volumes per 100 cc.

Oxygen is of doubtful value in most cases of shock since the arterial oxygen is normal. It is useful in cases with pulmonary injuries or complications and in cases of burns with exposure to noxious fumes.

Digitalis is not indicated for the treatment of shock.

Adrenal cortical hormone has been reported to be useful in the prevention of experimental shock and the treatment of clinical shock,[155, 13, 150] but more recent studies have disclosed no benefit from cortisone or ACTH in experimental hemorrhagic shock.[100, 68] On the other hand, shock appearing suddenly during anesthesia or operation has been attributed to the preoperative discontinuation of ACTH or cortisone in patients who had been previously treated with these steroid hormones.[14] The preoperative and postoperative administration of these hormones has been recommended to avoid shock in such patients.[14] There is experimental evidence suggesting that the effectiveness of nor-

epinephrine is dependent on an adequate supply of adrenal corticohormone Potentiation of norepinephrine by adrenocortical steroid hormones was reported in patients in whom adrenal insufficiency due to prolonged shock and myocardial infarction caused failure of response to vasopressor drugs [128] Occasionally these steroid hormones are life saving in shock associated with the toxemia and high fever of bacteremias until antibiotics control the causative infection Cures of the Waterhouse Friderichsen syndrome have been credited to cortisone [144] Corticotrophin has been used to permit discontinuation of norepinephrine after shock has been controlled by the latter [310]

Antibiotics are of primary importance in the treatment of shock due to or complicated by infection In addition there is some experimental evidence suggesting that antibiotics may have a protective action in shock independent of their antibacterial effect [■]

Hypothermia [117] induced by body cooling to 30 to 32° C with the aid of antihistaminics such as Phenergan and with chlorpromazine (Thorazine) has been employed in the treatment of traumatic shock During hypothermia maintained for two or three days, wounded men have been transported to distant hospitals subjected to necessary surgery and subsequently rewarmed slowly to normal body temperatue

SYNCOPE

Syncope is characterized by a sudden and usually unexpected loss of consciousness and of locomotion If the subject is upright he falls Fainting swooning and neurocirculatory failure are used synonymously with syncope Certain instances of primary or neurogenic shock are associated with syncope

Syncope is usually a form of hyperacute circulatory failure due to extreme ischemia or anoxia of the brain It may also be caused by severe traumatic, metabolic or psychologic disturbances As a rule syncope results from an extreme fall in blood pressure or pronounced slowing or standstill of the heart The erect position extreme exertion and environmental heat are usually predisposing or precipitating factors

1 Vasodepressor Syncope

(a) Psychic or Neurogenic Fainting This is the simple faint of psychic or reflex (neurogenic) origin, the so-called vasovagal syncope [11] Fright pain or other powerful emotions, the sight of blood operations, etc , the experience of physiologic tests or instrumentation are among the causes of this type of fainting Syncope in these cases is the result of a sharp decline in blood pressure, possibly mediated by way of the carotid sinus It always occurs when the patient is in the erect position There are premonitory symptoms such as weakness nausea, sweating, pallor Slowing of the pulse and heart block may develop but these are not responsible for the syncope

This type of vasodepressor syncope is observed in the acute circulatory collapse which sometimes follows moderate venesections (300 to 900 cc blood), e g occasionally in healthy blood donors [205] The cardiac output may be only slightly diminished or unchanged as *reflex peripheral vasodilatation* [99] results in an increased speed of circulation whereby a relatively normal venous return is maintained Syncope is due to an *extreme fall in blood pressure associated with a corresponding diminution in peripheral resistance* This is to be contrasted with the sharp fall in cardiac output and the clinical picture of shock which follows the loss of larger amounts of blood (1500 to 2000 cc or more) [17] While the actual faint, i e , the loss of consciousness is due to cerebral ischemia caused by the fall in blood pressure, the associated symptoms such as pallor, nausea, and sweating are due to generalized stimulation of the autonomic nervous system possibly by some efferent arc from the brain (hypothalamus?)

Under the heading vasodepressor syncope are also included cases of primary shock (p 307) fainting with onset of acute infections, with strenuous exercise, during pregnancy, or pleural punctures and after vasodilating drugs such as nitrites and nitroglycerin Rarely a pregnant woman may faint when she lies flat on her back This has been attributed to stimulation of sensory receptors in the abdomen by the enlarged uterus and to pooling of blood in the lower extremities by pressure of the uterus on the inferior vena cava [190]

(b) Carotid Sinus Syndrome Infrequently, spontaneous attacks of unconsciousness result from hypersensitivity of the carotid sinus [208 59] These attacks can be reproduced by pressure over the carotid sinus In normal persons such pressure causes only a slight reduction in pulse rate (less than 6 beats per minute) and only a

slight reduction in blood pressure (less than 10 *mm Hg*) *The carotid sinus tends to become* sensitive in individuals past middle age and especially in those with hypertension or *atherosclerosis It is also possible that the end* organs (effector organs) such as the heart and blood vessels rather than the carotid sinus become *hypersensitive In subjects with a* hypersensitive carotid sinus the slightest pressure, such as that due to the passage of a *razor over the neck bending or turning of the* head in certain positions a high or tight collar may induce dizziness or syncope [33] Similar attacks *rarely result from the pressure* of an enlarged cervical gland or tumor [134] Tests of carotid sinus sensitivity should be *performed* with caution [4] In patients with a *thrombosis of one internal carotid artery* syncope may follow compression of the other *internal carotid artery* below the sinus but not after compression of the affected side [133] Syncopal attacks often associated with convulsions and attributed to a hypersensitive carotid sinus may occur in so-called pulseless disease [6, 103, 1, 4, 83] in which thrombosis of the carotid and subclavian arteries is secondary to panarteritis of unknown etiology

Carotid sinus hypersensitivity may result in (a) vasodepression with a sharp fall in blood pressure (b) cardiac slowing cardiac standstill or heart block with or without ventricular stand till or (c) reflex cerebral ischemia with convulsions and *focal neuro*logic signs Each reaction type may cause syncope The last or cerebral type of carotid sinus syncope *is unaccompanied by* changes in pulse or blood pressure and is associated with slow waves in the electroencephalogram

Rarely a *lesion on an afferent vagal arc* induces syncope by a vagovagal reflex by way of the carotid sinus In the case reported by Weiss and Ferris [59] *a patient with an esopha*geal traction diverticulum experienced attacks of fainting and cardiac standstill when swallowing The attacks could be reproduced by artificial distention of the esophagus and prevented by atropine Similar attacks may occur in patients with disease of the biliary tract [59] Glossopharyngeal neuralgia occurring with swallowing or talking was associated in one case with bradycardia cardiac arrest and syncope due to a carotid sinus reflex *in which the glossopharyngeal nerve was the* afferent arc [165] Intracranial section of the glossopharyngeal nerve on the affected side relieved the neuralgia and abolished the paroxysms of cardiac arrest and syncope

2 Postural Syncope and Chronic Orthostatic *Hypotension*

Postural syncope or orthostatic hypotension may be classified as (1) transient and (2) chronic orthostatic hypotension a definite clinical syndrome

Prolonged standing in a fixed position may result in syncope *even in the normal person* Arising from bed after a prolonged illness often causes faintness or syncope Cardiac asystole *and syncope may occur following an* episode of strenuous physical exertion [6, 44] In these instances syncope is probably due to pooling of blood in the vessels of the lower *extremities which is ordinarily prevented by* strong muscle tone by the pumping action of the *muscles* which aid the venous return to the heart and by normal vasoconstrictor adjustments which occur when the body assumes the erect position

Chronic orthostatic hypotension [51] or postural hypotension [illegible] is a chronic clinical syndrome characterized by an extreme fall in blood pressure dizziness and syncope as soon as the patient attempts motionless standing The pulse is usually unchanged during syncope but orthostatic tachycardia atrial fibrillation and ST segment depression in the electrocardiogram have been described

Chronic orthostatic hypotension is often due to serious underlying disease of the central nervous system [47] It may be *secondary* or *idiopathic* Secondary chronic orthostatic hypotension is observed most commonly in diabetic patients with neuropathy but also in patients with tabes dorsalis syringomyelia *Addison s disease and Simmonds disease* [186]

Idiopathic Chronic Orthostatic Hypotension There is also a definite syndrome of idiopathic *chronic orthostatic hypotension* which is characterized by the triad of anhidrosis impotence and orthostatic hypotension causing syncope [41, 175] This *occurs very predomi*nantly in males usually between the ages of 40 and 70 When the patient stands there is an abrupt progressive fall in blood pressure associated with weakness vertigo blurred vision and syncope The nausea and pallor which usually precede the vasodepressor faint are absent There is little acceleration of the pulse rate and the cardiac output *may fall* abnormally Lack of perspiration may be

partial or virtually complete is usually bilateral but may be unilateral Pilocarpine may induce sweating when heat does not Nocturia and incontinence may be associated with the impotence Orthostatic tachycardia may be associated[178] Symptomatic discomfort is usually most severe when the patient arises in the morning or after meals and exercise and in warm weather Pupillary abnormalities such as Horner s syndrome or other abnormal pupillary reactions may be present These various findings indicate that this form of chronic orthostatic hypotension is due to a disturbance in sympathetic innervation[181] (asympathicotonic hypotension[15]) The underlying pathologic lesion has been thought to lie in the hypothalamus where the sweating center and a subcortical vasomotor center are situated but may be due to high thoracic lesions of the spinal cord[104] Vercl[20] presented evidence which suggested that the disorder is due to a central failure of the carotid sinus reflex It has been demonstrated that patients with chronic orthostatic hypotension do not pool more blood in the lower portion of the body than do normal subjects[47, 191] But there is a deficiency in the reflex arteriolar and venous constriction which should compensate for the normal tendency to pooling of blood with assumption of the upright position[1] This results in a fall in blood pressure which is intensified by a reduction in the cardiac output[99, 155] due to a diminished venous return[1, 5] Deficiency of the vasoconstrictor reflex has been related to a sharp diminution in the secretion of norepinephrine and epinephrine[123]

3 Cardiac Syncope

This type is characterized by sudden loss of consciousness with slight or no premonitory symptoms It is due to cerebral anemia caused by ventricular asystole or ventricular fibrillation The underlying causes are either (a) heart block or ventricular fibrillation with Adams Stokes syndrome (p 390), (b) disorders of the heart beat such as sinoatrial standstill or sinoatrial block (p 383) paroxysmal tachycardia or atrial fibrillation[26] (c) frequent premature beats (d) calcific aortic stenosis and (e) ball valve thrombus and pedunculated tumor of the left atrium Cardiac arrest occurs because of failure of the ventricular pacemaker in cases of heart block or because of ventricular asystole due to carotid sinus and vagal reflexes The syncope of the Adams Stokes syndrome may be due to either ventricular standstill or fibrillation (p 377) In paroxysmal tachycardias especially atrial fibrillation loss of consciousness occurs either at the onset or end of the attack owing to ventricular standstill because of failure of the pacemaker with change of rhythm[26] When frequent atrial premature beats are encountered between syncopal attacks the attacks themselves are often associated with paroxysmal atrial tachycardia or fibrillation The syncope of aortic stenosis is usually due to relative cerebral ischemia on exertion but may be caused by reflex cardiac standstill through the carotid sinus or by heart block with ventricular arrest Mechanical obstruction of the mitral orifice especially when there is concomitant mitral stenosis, accounts for syncope in cases of ball valve thrombus or pedunculated tumor of the left atrium Obstruction and syncope are precipitated by change of bodily position

4 Anoxic Syncope

This includes cases of syncope occurring in high altitudes syncope with extreme exertion, or syncope on exertion in patients with underlying congenital heart disease aortic stenosis or decompensated chronic pulmonary disease In cases of *congenital heart disease* with a right to left shunt, such as the tetralogy of Fallot syncope may occur with exertion because of increased arterial oxygen unsaturation and consequent cerebral anoxia The increased muscular activity of exercise causes the venous blood leaving the muscles to become excessively unsaturated with oxygen This blood is shunted into the systemic circulation and further reduces the arterial oxygen saturation In *aortic stenosis* there may be maximal cardiac output and cerebral blood flow at rest With exercise the required increase in cardiac output cannot be effected at the same time that more blood may be shunted to the active muscles thus there is less for the cerebral circulation The effort syncope occurring during exercise in *cor pulmonale* may similarly be due to cerebral anoxia and ischemia caused by inability to increase the cardiac output combined with underlying hypoxemia The possible role of hyperventilation and hypocapnia or of hypercapnia is uncertain When syncope occurs in cor pulmonale as a result of depression of

respiration by morphine or the inhalation of oxygen the syncope is due to hypercapnia (carbon dioxide retention)

5 Tussive Syncope[131 132 133 11]

Loss of consciousness may occur promptly after a paroxysm of cough especially in patients with obstructive emphysema or other obstructive lesions of the trachea such as aneurysm or tumor It may also occur in children and in subjects with hysteria who bear down with glottis closed The loss of consciousness occurs usually during a period of acute hypotension following cessation of cough[132] When obstructive lesions of the trachea or bronchi or voluntary obstruction prevents rapid emptying of the thorax a paroxysm of coughing builds up such a high intrathoracic pressure that the venous return to the heart is obstructed with resultant fall in left ventricular output cerebral ischemia and syncope The intrathoracic pressure may exceed 300 mm Hg well above the arterial blood pressure Recent studies suggest that there is a concomitant marked rise in spinal fluid pressure and consequently in intracranial pressure and that the syncope is actually due to direct impairment of cerebral blood flow rather than to obstruction of the cardiac output by intrathoracic hypertension[132]

6 Hyperventilation Causing Syncope

Hyperventilation often occurring involuntarily may be associated with syncope Such syncope is seen most frequently in adolescent girls and young women of neurotic temperament but I have observed it also in older women and in men The syncope usually develops gradually often preceded by dizziness and the loss of consciousness may be incomplete and is generally very brief A careful history may reveal other manifestations of the hyperventilation syndrome such as numbness and tingling of the hands feet and face visual disturbance or tetany The syncope is probably due to the diminished blood flow caused by low blood carbon dioxide tension (hypocapnia) but an associated fall in blood pressure may be important

7 Other Types of Syncope

Under this heading may be included cases of syncope due to severe head injuries to severe local vascular disease of the brain to drug sensitivity (e g after procaine injection) to hypoglycemia caused by insulin shock or an Addisonian crisis Postural hypotension induced by atropine has been reported[109 136]

8 Hysterical Fainting

Hysterical fainting is a special type of loss of consciousness of profound psychologic origin It occurs without alteration of pulse or blood pressure and without electroencephalographic abnormalities[171] It may be due to hyperventilation to neurogenic vasodepressor reflex or to closure of the glottis as in tussive syncope

9 Aviation and Syncope

Syncope presents an important problem in flying especially for pilots In a study of 500 cases of syncope involving pilots and air crew 42 per cent were interpreted as primarily of emotional origin 24 per cent as primarily neurogenic 31 per cent as primarily cardiovascular and 3 per cent unclassified[172] Hyperventilation of emotional origin was a frequent factor in the production of convulsions

Directly associated with aviation are the cases of syncope due to cerebral anoxia induced by low atmospheric pressure[172] when flying at great heights or by positive acceleration in the long axis of the body (blackout) or when the plane decelerates during ascent from a sharp dive at maximum acceleration During rapid ascent of a plane decompression with release of nitrogen and other gaseous bubbles from solution in the blood may cause aeroembolism with cerebral vascular occlusion and possible syncope or death

Differential diagnosis of the various types of syncope can usually be made by a very detailed history of the events and symptoms preceding during and after the attack by a careful examination and sometimes by special tests (carotid sinus pressure electrocardiography electroencephalography etc) and by observing the effects of drugs An excellent discussion has been presented by Engel[81]

TREATMENT OF SYNCOPE

A recumbent or head down position abolishes most attacks of syncope Preferably the patient should be placed in the Trendelenburg position or he should be in a supine or prone position with his legs elevated[133]

In the cases of frequent syncopal attacks (postural hypotension) the cause should be treated if possible (large varicose veins Addison s disease) Leg bandages and abdominal binders may be employed to help the venous

return Training the patient with a head up bed 20 degrees above horizontal has been recommended in the treatment of chronic postural hypotension [5] The most effective treatment is the continued administration of the sympathomimetic (vasoconstricting) drugs

Isopropylnorepinephrine (Isuprel) 10 to 15 mg may be taken sublingually to abort an attack if there is adequate warning Ephedrine sulfate 25 mg or amphetamine 5 to 10 mg [37] may be given orally one to four times daily especially in the earlier part of the day Paredrine hydrobromide has a more sustained action and less central effects and may be given orally in 60 mg doses three times daily Sometimes it is more effective to give a single daily dose of 100 to 160 mg of Paredrine one-half hour to an hour before arising Similar advantages apply to Neo-synephrine which has been found effective in 20 mg doses three times daily (following larger initial doses) after ephedrine and amphetamine had failed to control the syncopal attacks Paredrine and Neo synephrine may be used parenterally to control the syncope of spinal anesthesia (p 307) It may be necessary to combine the sympathomimetic drugs with mild sedatives to counteract nervous excitation or sleeplessness

The sympathomimetic drugs are also used in cases of syncope due to a hypersensitive carotid sinus syndrome In addition tincture of belladonna 10 to 15 minims three times daily or atropine sulfate 0 3 mg ($\frac{1}{200}$ grain) three times daily may be helpful In some instances surgical denervation of the carotid sinus (after a preliminary therapeutic test with procaine infiltration) may be advisable to eliminate the attacks [3] Greeley et al [85] reported relief of the carotid sinus syndrome within hours or a few days after irradiation of one or both carotid sinuses Two or three treatments were given on alternate days a dose of 200 roentgens (measured in air) was administered to a 5 cm square portal and the total dosage averaged 500 roentgens if one side was treated and 800 roentgens if both The factors were 200 to 220 kV with a 2 mm filter of copper and a 1 mm filter of aluminum and a 50 cm target skin distance

The use of molar sodium lactate epinephrine Isuprel [178] and other sympathomimetic drugs in syncope of Adams Stokes syndrome is discussed elsewhere (p 393) The use of an electrical cardiac pacemaker[219] may be undertaken when there are very frequent episodes of ventricular asystole despite sympathomimetic drugs Syncope due to procaine sensitivity should be treated with barbiturates and not with sympathomimetic agents

CARDIAC ARREST (See pp 1108 and 394)

SUDDEN DEATH

Sudden death denotes the *quick* and *unexpected* termination of life This may include death instantaneously or within a few minutes sudden syncope with deepening and fatal coma or an acute illness without unconsciousness which is unexpectedly fatal within twenty four hours [146]

PATHOLOGIC PHYSIOLOGY

Sudden death results from sudden irreversible and intense cerebral anoxia The responsible mechanisms are similar to those causing syncope or shock but more rapid and severe and hence irreversible (But see p 583)

These mechanisms include (a) sudden local traumatic toxic vascular or metabolic injury to the brain (b) exsanguinating hemorrhage with medullary anoxia or pericardial hemorrhage causing cardiac tamponade (c) massive pulmonary embolism with obstruction of blood flow and cerebral anoxia (d) ventricular asystole

The last group is of special interest to the cardiologist Often in instances of sudden death postmortem examinations fail to reveal the cause Coronary atherosclerosis or other cardiac disease is frequent but insufficient in degree to explain the sudden end [123] It is believed that death in such cases is due to a physiologic disturbance resulting in cessation of the heart beat Cessation of the heart beat may be due to cardiac standstill or to ventricular fibrillation [194]

Belief in the causal relationship of ventricular fibrillation to sudden death is based on (a) observations of this arrhythmia prior to death of experimental animals especially following coronary artery ligation,[91] and (b) its presence in electrocardiographic tracings taken by chance in patients who died during the recording [82] On the other hand Weiss [97] stressed the possible relation of cardiac standstill (caused by carotid sinus and vagal reflexes or heart block) to sudden death Cardiac standstill is sometimes observed in

exposed hearts when sudden death occurs during operation In a recent study of terminal electrocardiograms Stroud and Feil[184] found that sudden death was associated as often with cardiac standstill as with ventricular fibrillation In the presence of coronary or cardiac disease the myocardium is especially susceptible to both of these forms of sudden death

ETIOLOGY AND PATHOLOGY

Cases of sudden death are usually seen by the coroner A physician summoned to see an individual who died suddenly must be cautious in excluding factors of violence and poisoning even when there is no overt evidence and even when the *individual was known to have some competent producing* cause No death certificate should be issued without the approval of the coroner or official medical examiner if the physician was not in attendance at the time of death or if there is a claim of trauma as the cause of death

Excluding deaths due to trauma or poisoning the commonest causes of sudden death[14, 168] are (1) diseases of the heart and aorta (2) respiratory diseases especially pneumonia (3) cerebral complications especially those associated with hemorrhage (4) diseases of the digestive and urinary tracts

Among the precipitating causes are severe exertion[107] especially in warm weather *straining at stool anesthesia aspiration of* body cavities fright and other powerful emotions

Heart disease is by far the commonest cause of sudden death and coronary atherosclerosis accounts for at least 60 to 80 per cent of these sudden cardiac deaths[57, 149] Attention has recently been drawn to the frequency of sudden death in young men with advanced coronary atherosclerosis but without coronary occlusion or myocardial infarction[75, 14, 217] But sudden death may result at the onset of an acute coronary occlusion or from ventricular rupture following myocardial infarction Massive pulmonary embolism is a common cause of death in patients with acute myocardial infarction as well as in patients bedridden for other reasons

Calcific aortic stenosis is the commonest valvular lesion associated with sudden death but the latter may occur with any other valvular or myocardial disease

Sudden death occurs more often with syphilitic than with rheumatic aortic insufficiency probably because of the accompanying ostial stenosis in the former Sudden death in syphilitic aortitis[119] may also be due to rupture of an aortic aneurysm

Among natural causes of sudden death to be remembered are acute respiratory infections and congenital heart disease in infants coronary atherosclerosis rupture of a congenital cerebral aneurysm tubal rupture in ectopic pregnancy brain tumor and fulminating meningitis in young adults, coronary artery disease and syphilitic aortitis dissecting aneurysm of the aorta and acute gastrointestinal bleeding in middle age and beyond

PART III

THE CARDIAC ARRHYTHMIAS

Chapter 13

DISTURBANCES IN IMPULSE FORMATION

CLASSIFICATION OF DISORDERS OF THE HEART BEAT

In general cardiac arrhythmias result from disturbances in impulse formation or impulse conduction and these may be further subdivided as follows

- I Disturbances in impulse formation
  - A Sinoatrial (sinus) rhythms (nomotopic rhythm)
    - 1 With abnormal rate
      - a Sinus tachycardia
      - b Sinus bradycardia
    - 2 With irregular sequence of impulse formation
      - a Sinus arrhythmia
      - b Sinus arrest and atrial standstill
      - c Ventricular and cardiac standstill
  - B Ectopic rhythms (heterotopic rhythms)
    - 1 Escape rhythms (nodal rhythm and idioventricular rhythm)
    - 2 Premature contractions (extrasystoles)
    - 3 Paroxysmal tachycardia
    - 4 Atrial flutter
    - 5 Atrial fibrillation
    - 6 Ventricular tachycardia
    - 7 Ventricular fibrillation
- II Disturbances in conduction of the cardiac impulse
  - A Sinoatrial heart block
  - B Atrioventricular heart block (partial and complete)
  - C Bundle branch block
  - D Short P R interval with prolonged QRS

The above classification is based on the physiologic disturbances in the initiation and propagation of the cardiac impulse It is useful in the understanding of the associated electrocardiographic abnormalities From the practical viewpoint of bedside diagnosis it is simpler to observe whether the cardiac rhythm is regular or irregular and whether the rate is unusually rapid (tachycardia) unusually slow (bradycardia) or normal

Tachycardias which are regular include (1) sinoatrial (sinus) tachycardia (2) paroxysmal atrial tachycardia (3) ventricular tachycardia and (4) atrial flutter with 1 1 response or with unchanging degree of block Irregular tachycardias include (1) atrial fibrillation (2) atrial flutter with varying block and (3) sinus tachycardia with numerous premature beats

Bradycardias with regular rhythm include (1) sinus bradycardia (2) nodal rhythm (3) severe partial heart block with constant degree of block and (4) complete heart block Irregular bradycardias include (1) sinoatrial bradycardia with marked sinus arrhythmia or frequent premature beats and (2) partial heart block with frequent dropped beats or changing degree of block

Irregular rhythms with normal heart rate include frequent premature beats atrial fibrillation with ventricular rate slowed by digitalis sinus arrhythmia and partial heart block with dropped beats

SINUS TACHYCARDIA

The normal heart rate of adults at rest varies between 60 and 90 per minute while that of infants ranges between 100 and 150 Sinus tachycardia denotes that the cardiac impulse arises normally in the sinoatrial node but that the rate is increased above 100 per minute (adults) Knowledge of the individual s normal heart rate under given conditions is a better basis for determining the existence of tachycardia than arbitrary levels Ordinarily the heart rate in sinus tachycardia does not exceed 160 per minute a feature distinguishing it from that of paroxysmal atrial or ventricular tachycardia

The *electrocardiogram* is characterized by abbreviation of the P P intervals below 0 6

second and by recurrence of the P waves at regular intervals each followed by a QRS complex Occasionally, when the rate exceeds 150 per minute, the P waves may become fused with the preceding T wave The reduction in the cardiac cycle is chiefly at the expense of the diastolic period

Vagal depression and accelerator stimulation in varied degree account for sinus tachycardia

Physiologic sinus tachycardia results from emotion exercise digestion, and other causes Voluntary acceleration of the heart rate has been observed[27] Certain drugs such as atropine and amyl nitrite may be used clinically to produce sinus tachycardia Among pathologic conditions associated with sinus tachycardia are fever, hyperthyroidism, anemia acute hemorrhage shock congestive heart failure and cardiac neurosis Tachycardia on assumption of the upright position occurs in some cases of chronic postural hypotension (p 313) and occasionally in cases of pheochromocytoma (p 1025)

Examination of the heart and pulse discloses a regular rhythm with a rate exceeding 100 per minute Differentiation from other tachycardias with *regular* rhythm may be made from the electrocardiogram or surmised on clinical grounds (p 378) There may be no subjective symptoms, or there may be disagreeable palpitation fatigue and breathlessness as in other tachycardias (p 346)

The clinical significance depends on the basic cause The tachycardia subsides when the underlying cause is removed Sometimes tachycardia is noted without apparent cause An unsuspected hyperthyroidism or anemia may be responsible and the possibility of their presence should be investigated Occasionally a persistent sinus tachycardia disappears only after the elimination of tobacco alcohol excessive coffee or sympathomimetic drugs such as ephedrine, dextroamphetamine or the like

SINUS BRADYCARDIA

Sinus bradycardia denotes that the cardiac impulse arises normally in the sinoatrial node but that the cardiac rate is less than 50 per minute

The *electrocardiogram* is characterized by prolongation of the P-P interval to 1 second or more, but the P waves recur regularly and are each followed by QRS complexes Occasionally in bradycardias of vagal origin sinus arrhythmia (see below) is associated, and the P P intervals are somewhat irregular The P R interval tends to be prolonged in sinus bradycardia Slowing of the heart rate involves predominantly an elongation of diastole (T-P interval)

The *mechanism* is probably an increase of vagal tone or a diminution of sympathetic tone or both

Normally, heart rates of 50 per minute or less are sometimes observed during sleep and are not uncommon during pregnancy Sinus bradycardia is fairly common among those engaged in strenuous labor and among trained athletes Rates as low as 36 to 40 per minute have been observed in distance runners with normal hearts Under pathologic circumstances sinus bradycardia may be associated with cerebral lesions with increased intracranial pressure, coronary heart disease (occasionally) convalescence from infectious disease myxedema icterus and in patients treated with ACTH or cortisone

There are usually no clinical symptoms of sinus bradycardia but dyspnea palpitation, precordial pain dizziness, faintness or syncope may be associated with extremely slow cardiac rates[40] Syncopal attacks may be due to excessive bradycardia or cardiac asystole[40]

Examination of the heart and pulse discloses a regular rhythm with slowing of the heart rate below 50 per minute But the rate may be increased by exercise emotion atropine or any other factor which diminishes vagal or increases sympathetic tone

Sinus bradycardia must be differentiated from a slow nodal rhythm and from heart block The presence of the normal systolic collapse in the jugular vein and the absence of jugular pulsations during the long diastolic pause may be distinctive of sinus bradycardia in contrast to nodal rhythm or heart block In heart block, atrial pulsations may be visible in the cervical veins and atrial cardiac sounds may be audible during the pauses between heart beats The electrocardiogram is usually necessary for a definite diagnosis Sinus bradycardia may be indistinguishable from prolonged sinoatrial block with 2 1 rhythm (p 383)

Usually no treatment is necessary If syncope occurs treatment is that described under Adams-Stokes syndrome (p 390)

SINUS ARRHYTHMIA (PHASIC ARRHYTHMIA, JUVENILE ARRHYTHMIA)

The cardiac impulses arise normally in the sinoatrial node but their rhythmicity varies. This gives rise to alternating periods of slower and more rapid cardiac rates. The longest and shortest R-R intervals differ by 0.12 second or more. The variations are usually, but not always, related to respiration, the heart rate increasing with inspiration and diminishing with expiration (respiratory arrhythmia).

The *electrocardiogram* discloses P waves each followed by QRS complexes in normal succession, but the P-P intervals form alternate series of shorter and longer cycles. The changes in length are virtually confined to the T-P interval (Fig. 62). The configuration of the P wave may show slight alterations suggesting shifting sites of origin of the cardiac impulse, but all within the sinoatrial node. The P-R interval may be relatively longer after a short R-R interval, i.e., during the more rapid rates, than during the slower cycles. This has been related to the Wenckebach phenomenon[28] (p. 386) or to a lower origin of the impulse in the sinus node and therefore a lesser distance to the ventricular conduction system. On the other hand, strong vagal tone may also tend to prolong the P-R interval.

Mechanism. Careful analysis of electrocardiograms with normal sinus rhythm and rates under 80 per minute disclose that there is no absolute regularity and that cycle lengths vary slightly but definitely. This is probably due to physiologic phasic variations in the vagal (and sympathetic?) tonus. Sinus arrhythmia is merely an exaggeration of this normal tendency. A chronotropic inhibitory effect of the vagus nerve may cause a *shift of the pacemaker* from the cephalic position to the middle or tail of the sinoatrial node, as suggested by changes in the form of the P wave and as indicated by intracardiac electrocardiography.[43] Impulses from the respiratory center and lungs at the height of inspiration depress the vagus center and accelerate the cardiac rate. Sinus arrhythmia is commonest in hearts with bradycardia, presumably because there the vagal influence tends to be maximal. Sinus arrhythmia may be associated with other influences which affect vagal tonus independently of the respiratory phase.

Sinus arrhythmia occurs commonly among children and among the aged.[28] It is often observed during rheumatic fever, convalescence from infectious diseases, following digitalization, and in diseases of the brain with increased intracranial tension, all conditions associated with vagal stimulation or increased vagal tonus.

Clinically, sinus arrhythmia is recognizable by the fairly regular alternation of several rapid heart or pulse beats with a similar cycle of slower beats. The relation of the rapid beats to inspiration and the slow beats to expiration is diagnostic. Intensification of the arrhythmia by deep breathing or its abolition by breath holding, exercise or atropine may also be helpful in diagnosis. Rarely an electrocardiogram is required to distinguish with certainty sinus arrhythmia from atrial fibrillation with slow ventricular rate or from partial atrioventricular block with varying P-R interval.

As a rule sinus arrhythmia is of no clinical importance and requires no treatment. When accompanied by intense bradycardia, it may be associated with attacks of dizziness. When sinus arrhythmia results from vagal stimulation secondary to serious cerebral disease or the like, the outlook is that of the underlying disease.

Fig. 62. Sinus arrhythmia. A woman, aged 28, with diabetic acidosis but without heart disease. Lead III. Progressive decrease, then increase in length of cardiac cycles. Effect chiefly on length of T-P interval.

SINUS ARREST AND ATRIAL STANDSTILL

For general discussion of Cardiac Arrest see pages 391 and 1108.

Sinus arrest (sinoatrial standstill or sinus pause) denotes a pause in the cardiac rhythm due to a momentary failure of the sinus node to initiate an impulse.

The *electrocardiogram* is characterized by a

prolonged diastolic pause between two PQRST complexes which are entirely normal (Fig 63) The pause is not an exact multiple of the normal P P cycle

The *mechanism* is probably a reflex vagal stimulation through the carotid sinus or a direct stimulation of the vagal center

Sinus arrest may occur after gagging or stimulation of the pharynx It may be observed in patients with a hypersensitive carotid sinus Sinus arrest and sinus arrhythmia are sometimes associated both resulting from conditions which stimulate the vagus nerve

Sinus arrest is usually of no clinical significance but if the pause is sufficiently long dizziness faintness or even syncope may ensue

Clinically sinus arrest is recognized by the omission of a beat (dropped beat) at the cardiac apex as well as at the wrist Sinus arrest may be indistinguishable from sinoatrial block (p 383) It must be differentiated from the pause of dropped beats in partial heart block (p 385) and the compensatory pause following an early premature beat

Atrial standstill denotes a pause in atrial contraction, while the ventricle contracts in response to stimulation by its own pacemaker [47] Atrial standstill is secondary to either sinus arrest or sinoatrial block Magnasson[61] reported 3 cases of his own and 31 cases collected from the literature

The *electrocardiogram* shows a regular sequence of ventricular complexes, but one or more P waves are absent Bradycardia is commonly associated

Mechanism When the sinoatrial node fails to initiate an impulse or the impulse is blocked from reaching the atrium, there is no atrial contraction However a pacemaker of lower rhythmicity (infra) in the a v node bundle or ventricle, activates the ventricle and causes contraction

The *cause* of atrial standstill is usually digitalis or quinidine intoxication but organic heart disease is often present

Clinically, the rhythm is regular, but there may be intense slowing of the heart An electrocardiogram is essential for diagnosis When atrial standstill is due to digitalis or quinidine, these drugs should be stopped and if necessary, resumed later in smaller dosage

Fig 63 Sinus arrest or sinus inertia A man aged 73 with coronary artery disease Lead II Pauses without atrial or ventricular contraction Sinoatrial block not excluded but less probable because pauses are not multiples of normal P P interval There are associated conduction disturbances

ECTOPIC BEATS AND ECTOPIC RHYTHMS

All parts of the conduction system possess the property of excitability and rhythmicity, that is of initiating impulses and exciting contraction But the degree of rhythmicity, i e the rapidity with which impulses are formed and released, varies Normally the sinoatrial node has the greatest rhythmicity and dominates the rhythm of the heart It is therefore termed the pacemaker Lesser degrees of rhythmicity are possessed by the atrioventricular node, the a v bundle and the ventricular specialized tissue, in that order Thus while the s a node emits impulses at 70 to 80 per minute, the a v node initiates them at 40 to 60 per minute and the bundle and lower centers at less than 40 per minute The impulses released by these other centers are nullified by the more frequent sinus impulses However when the rhythmicity of the sinoatrial node is depressed or the rhythmicity of some other center of the heart is enhanced above that of the sinus node the lower center may control the heart rhythm and become the pacemaker Whenever isolated cardiac beats are excited by some center other than the sinus node, they are termed ectopic beats When a more continuous rhythm is initiated by a focus outside the sinus node it is termed an ectopic rhythm

ESCAPE RHYTHMS

Escape rhythms are those initiated by lower centers when the sinoatrial node fails to initiate impulses when its rhythmicity is depressed, or when its impulses are completely blocked When the a v node becomes the pacemaker for a single beat it is termed a nodal escaped beat, when it becomes pacemaker for a continuous period, nodal rhythm

appears. If the atrioventricular node activates the ventricles, whereas the atria are activated by the sinoatrial node, the rhythm is termed atrioventricular dissociation, not nodal rhythm. If the s a node and a v node are sufficiently depressed or fail to initiate impulses, a focus in the bundle or ventricles controls ventricular contraction either for isolated beats (ventricular escape) or for a continuous rhythm termed idioventricular rhythm.

Atrioventricular (Nodal) Rhythm. Wandering Pacemaker

Experimentally, nodal rhythm can be produced by cooling, clamping, or chemical destruction of the sinoatrial node[5, 16] and occasionally by vagal stimulation. The rhythm of a lower center thus released represents an escape rhythm, and the cardiac rate is slow, averaging 40 to 60 per minute.[9] But nodal rhythm may be associated with a normal rate and a v nodal tachycardia has also been described (pp. 344–345).

Occasionally, isolated beats are controlled by the a v node while others are controlled in their normal fashion by the sinoatrial node. This phenomenon is termed wandering or shifting pacemaker. Such shifts in pacemaker occur whenever the rates of impulse formation in the sinoatrial and atrioventricular nodes are almost identical. Then slight physiologic changes in vagal tonus may modify these rates of impulse formation sufficiently to permit one or the other of the nodal centers to gain control of the heart rate.[16, 31] Pressure on the carotid sinus or eyeball (oculovagal reflex) may induce transient a v beats or rhythm interspersed among stretches of sinus rhythm. Occasionally the slight variation in vagal tonus caused by sitting up from the recumbent position may result in transient nodal rhythm.[■] The intravenous administration of Neo-synephrine in humans, presumed to cause reflex vagal stimulation, suppresses the sinus node with consequent bradycardia or atrial standstill, or there may be wandering of the pacemaker or nodal rhythm.[17] Other beats or rhythms dominated by the a v node are nodal premature beats (p. 335) or nodal tachycardia (pp. 344–345). These represent enhancement of nodal rhythmicity rather than primary depression of the sinus node, but both may coexist.

The Electrocardiogram. With *isolated nodal escape beats* there is a sinus pause followed by a normal QRS complex, while the P wave is usually inverted and precedes, fuses with, or follows the QRS complex (Fig. 64). The P wave is usually altered in configuration because the origin of the atrial activation wave in the a v node and its course differ from the normal. As a rule the s a node resumes its role as pacemaker after isolated nodal or other ectopic atrial escape beats. But several beats with varying position and configuration of the P wave occur before sinus rhythm is reestablished. The path of the pacemaking stimuli may be followed by esophageal leads and atrial vectorcardiograms.[17]

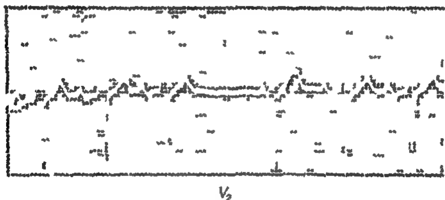

Fig. 64. Sinus arrest after third beat. This is followed by an escaped nodal beat.

With continued a v nodal control (*nodal rhythm*) the QRS complexes are normal and follow in regular sequence at a rate of 40 to 50 per minute. This denotes that the cardiac impulse follows its normal course in depolarizing the ventricles. On the other hand, the a v nodal impulse must be conducted retrograde toward the s a node and atria in acti

vating these chambers Such caudiocranial conduction in nodal rhythm may be demonstrated by esophageal leads[86] This modifies both the position and configuration of the P waves It is assumed that when the cardiac impulse arises in the head or coronary sinus portion of the a v node (coronary sinus rhythm)[78] atrial depolarization precedes that of the ventricles and the P wave precedes the QRS, when it arises in the body or midportion, both atria and ventricles are simultaneously activated and the P wave is lost in the QRS, when the impulse arises in the tail of the a v node it reaches the ventricles prior to the atria and the QRS precedes the P wave But even when the P wave in nodal rhythm precedes the QRS as it does normally the P-R interval is shortened (0 11 second or less) because the distance traversed by the impulse from the a v node to the ventricles is always shorter than from the sinus node In coronary sinus rhythm i e when the impulse

Fig 65 Nodal rhythm A man aged 56 with healed anterior wall infarction Lead II Inverted P waves following ventricular deflection

arises in the uppermost portion of the atrioventricular node the P R interval is within the range of normal The retrograde direction of the a v nodal impulse as it activates the atria causes an inversion of the P wave in leads II and III (Fig 65) The effect on lead I depends on whether the depolarizing process runs from right to left as normally or is altered accordingly P_1 may be upright diphasic or inverted

Rarely a v nodal rhythm is coupled with premature contractions of sinoatrial atrial or ventricular origin[..., 19] Nodal rhythm may be associated with atrioventricular block[47] Upper atrioventricular nodal beats have been precipitated by ventricular extrasystoles with retrograde conduction[78]

Clinically, nodal rhythm is observed in conditions which depress the rate of impulse formation in the sinoatrial node or which prevent the sinus impulses from reaching and activating the atria (sinoatrial block) Usually underlying heart disease is present but physiologic or pathologic influences which increase vagal tone are contributory or precipitating factors in the initiation of a-v rhythm Hypertension and coronary artery disease are commonly found in cases of coronary sinus rhythm[78] A v rhythm has been attributed to the impairment of the blood supply to the sinoatrial node especially in elderly persons with high vagal tonus In such persons deep breathing digitalis or anesthesia may induce a v (nodal) rhythm Nodal rhythm has been observed in association with acute coronary occlusion[53] in various infectious diseases[..] especially active rheumatic fever[..] and after atrial flutter But a v nodal rhythm also occurs in apparently normal hearts, both as a result of vagal stimulation by carotid sinus or ocular pressure[37] and paradoxically after the parenteral administration of atropine[..] A v nodal rhythm has also been observed after the administration of digitalis[66] quinidine[33] and Neo synephrine[17]

Despite this variety of circumstances under which it may develop, actually a v rhythm occurs relatively infrequently It is almost always a transient phenomenon alternating with sinus rhythm Usually a-v rhythm persists for brief runs but occasionally it may persist for several days or weeks

Clinical symptoms are uncommon and rarely distressing But there may be disturbing palpitation or a choking sensation or fullness in the neck due to simultaneous ventricular and atrial contraction The latter forces the atrial contents into the cervical veins as the tricuspid valve is shut For this reason also there may be an intensification of the first cardiac sound and there may be a prominent pulsation in the cervical veins due to the abnormal amplitude of the atrial (a') wave

Diagnosis usually requires electrocardiographic study (p 327) but a v rhythm may be suspected from the bradycardia and from the atrial systolic regurgitation waves in the cervical veins A jugular pulse tracing with simultaneous electrocardiogram may show "a waves occurring synchronously with the QRS complexes Bradycardia due to heart

block may be distinguished by the presence of atrial waves in the long diastolic intervals between beats. Esophageal electrocardiograms indicate not only the presence of nodal rhythm but the probable site of origin and course of the impulse.

Treatment either is unnecessary, is directed toward the underlying disease (e.g. coronary disease) or consists in removal of the causative agent (digitalis). Nodal rhythm can usually be abolished by atropine or exercise.

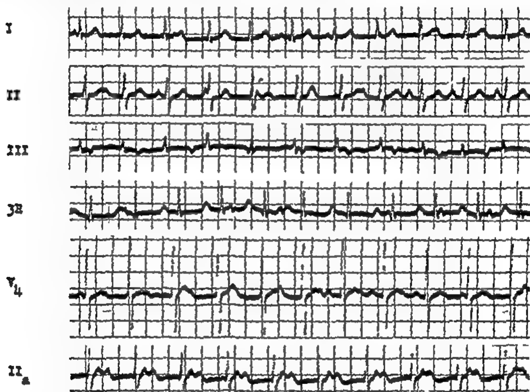

Fig 60 Complete atrioventricular dissociation in acute rheumatic fever. Atrial rate (lead V 3R) 100 per minute, ventricular rate 120 per minute. In lead II there is first degree heart block with P R 0.3 second.

Atrioventricular Rhythm with Reciprocal Beats. In most instances of a-v (nodal) rhythm the nodal impulse activates the ventricles and also is transmitted retrograde to activate the atria. Occasionally this same retrograde nodal impulse, after effecting an atrial contraction, may retrace its path to the a-v node and continue through the bundle and bundle branches to induce another ventricular contraction.[21] This additional contraction is termed a reciprocal beat, and when many such beats occur there is a reciprocal or reciprocating rhythm.[7]

Reciprocal beats occur as a rule in that type of a-v rhythm in which the ventricles contract before the atria and in which the atrial activation is so delayed that the ventricle is no longer refractory and can respond to the returning atrial (nodal) impulse. Often there is a progressive increasing delay in retrograde conduction until finally a reciprocal beat occurs, resembling a reversed Wenckebach period (p 386). This delay in retrograde conduction of the a-v nodal impulse is usually induced by carotid sinus pressure or digitalis therapy.

The *electrocardiogram* shows the QRS complex of a-v rhythm followed by an abnormal (nodal) P wave after an interval which is longer than usual. This P wave is then followed rapidly by another QRS complex. The result is a succession of QRS complexes (ventricular beats) resembling bigeminy or coupling (p 332) ordinarily seen when a premature ventricular beat (extrasystole) follows a normal ventricular contraction.[35] The term "return extrasystole" is sometimes applied to the reciprocal beat.

Atrioventricular Rhythm and Atrioventricular Dissociation. I have stated that in atrioven

tricular rhythm the nodal impulse is usually conducted retrograde as well as forward and activates the atria as well as the ventricles Sometimes possibly as a result of retrograde (unidirectional) atrial block the nodal impulse activates the ventricles but not the atria [77] In such cases the sinus node may continue to activate the atria while the a v node controls only the ventricles in spite of the more rapid stimulus formation in the a v as compared with the s a node This independence of atrial and ventricular contractions in response to different pacemakers is atrioventricular dissociation (Fig 66) The ventricular rate, controlled by the a v node, may exceed that of the atria which are responding to a depressed sinoatrial node This type of a v dissociation is usually the result of digitalis or of infections such as rheumatic fever Another form of a v dissociation may result from complete atrioventricular block in which neither sinus nor a v nodal impulses reach the ventricles and the latter respond to a pacemaker in the bundle below the block (see idioventricular rhythm) Complete a v block with dissociation is distinguished by more frequent atrial contractions than ventricular, while in the type under discussion the ventricular rate is more rapid than the atrial

A V Dissociation with Interference Beats (Interference Dissociation) In the cases of atrioventricular rhythm and dissociation, an occasional sinus impulse may succeed in activating the ventricles as well as the atria despite the higher rate of impulse formation in the a v node The ventricular contraction in response to a sinus impulse interrupts the usual contractions in response to a v nodal impulses and is termed an *interference beat* The combination of interference beats with atrioventricular dissociation is termed *interference dissociation*[57] (Fig 67)

Atrioventricular dissociation is most commonly due to digitalis toxicity and occasionally to quinidine It may be observed in association with rheumatic carditis or coronary heart disease

Ordinarily in a v rhythm with dissociation, the slow sinus impulses cannot activate the ventricles because the a v node and lower conduction system are refractory when the sinus impulse arrives Because of continuous although slight variations in the rate of formation of sinus impulses and similar variations in the time relationship of sinus and a-v nodal impulses, a sinus impulse occasionally arrives at the a v node when the latter is not refractory, traverses the bundle and its branches and activates the similarly nonrefractory ventricles The sinus ventricular beat follows the a v nodal ventricular beat after an abnormally brief interval and gives the appearance of a coupled extrasystole (p 332) Dressler and associates[20] described 2 cases of atrioventricular dissociation with interference in the presence of 2 1 atrioventricular block This arrhythmia, sometimes erroneously diagnosed as complete heart block differs from ordinary interference dissociation in that the ventricular rhythm is slower than sinus rhythm but faster than one half the sinus rhythm

The *electrocardiogram* in interference dissociation is characterized by QRS complexes of normal configuration (a v nodal origin) occurring independently of and at varying intervals from normal sinus P waves The P wave may be lost in one (nodal) QRS and then follow successive (nodal) QRS complexes at progressively longer intervals until it occurs so late that it is followed by a (sinus) QRS complex which occurs prematurely in response to the sinus impulse The irregularity simulates premature atrial systoles These interference beats are distinguished from reciprocal beats (p 329) by the normal upright sinus P waves between the coupled QRS complexes (Fig 67) In reciprocal beats the premature QRS follows a returning a v nodal impulse which is represented by a deformed or inverted P wave Both accompany a v nodal rhythm but reciprocal beats occur only if there is no complete retrograde atrial block to the a v nodal impulse while interference beats occur only in the presence of such a retrograde block which is responsible for the a v dissociation Both reciprocal and interference beats occur in a-v rhythm in which the ventricular rate is slightly more rapid than the atrial and which is usually the result of sinoatrial depression or sinoatrial block caused by digitalis or in acute infections such as rheumatic fever

Idioventricular Rhythm

We have seen that depression of the rate of impulse formation in the sinoatrial node or block of sinoatrial impulses may permit the a v node to become the pacemaker of the heart for isolated beats (nodal escape beats)

or for continuous periods (a v nodal rhythm) Similar depression of the a v as well as the sinoatrial node (carotid sinus or ocular pressure) or a block of a v conduction (digitalis organic lesions) may permit still lower automatic centers in the main a v bundle or in the specific tissue of one of the ventricles to assume control of the heart beat When single ventricular impulses pace the heart isolated ventricular escape beats are observed When the lower center maintains more continuous control there is idioventricular rhythm or ventricular automatism The atria remain under sinoatrial control

Idioventricular rhythm is observed most commonly in cases of atrioventricular block (p 386) in which impulses from the s a or a v node are prevented from reaching the ventricles The pacemaker probably arises in the a v bundle below the site of obstruction for the configuration of the QRS is normal (*supraventricular type*) denoting a normal pathway of the wave of ventricular excitation The ventricular rate is usually less than 40 per minute Since the atria are independently activated by the sinus node the P waves are of normal configuration and occur at rates of 70 to 80 per minute Thus as in some cases of a v rhythm idioventricular rhythm is accompanied by atrioventricular dissociation Since the ventricular complex in idioventricular rhythm is usually identical with that of a v rhythm the two conditions may be indistinguishable when there is a v dissociation The ventricular rate is usually more rapid (above 40) in a v rhythm there is usually a prolonged pause (preautomatic pause) before the onset of ventricular automatism, and carotid sinus pressure (vagal stimulation) usually slows the ventricular rate in a v but not in idioventricular rhythm since the vagus does not extend below the a v node Retrograde conduction to the atria rarely if ever occurs in idioventricular rhythm but is common in a v rhythm In the presence of such retrograde conduction a v rhythm is generally easily distinguishable by the presence of P waves usually inverted in leads II and III at abnormally short distances preceding or following the QRS complex

When the idioventricular pacemaker is situated below the bundle of His the QRS complex has a bizarre configuration characterized by widening slurring and notching while the T wave is often opposite in direction to the main QRS deflection This abnormal appearance denotes an abnormal origin and course of ventricular excitation (p 335) The electrocardiographic appearance of the ventricular *complex (QRST) is identical with that of an* extrasystole (premature beat) but may be distinguished by its occurrence after a prolonged pause instead of prematurely In both of these the P wave is usually obscured in bundle branch block the QRST is also similar but follows a normal sinus P wave after a normal or slightly prolonged P R interval If the pacemaker is above the bundle of His and there is complicating bundle branch block the QRS complex may simulate that of an idioventricular pacemaker

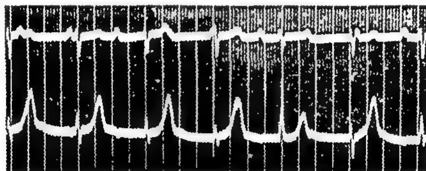

Fig 87 A v dissociation with interference beats Leads III and IV taken simultaneously Atria responding to sinus and ventricles to a v node at slightly different rates (a v dissociation) P R relationship constantly changing After four ventricular responses to the a v node the ventricle responds to a sinus impulse (interference beat) and shows a different (normal) configuration

Prolonged idioventricular rhythm arising in a center in the ventricles below the main bundle rarely occurs in humans as an escape rhythm On the other hand ventricular foci may gain control of the heart as a result of

factors which so increase the irritability of the ventricular conduction tissue that its rate of impulse formation exceeds that of the sinus or a v nodes The resulting rhythms are discussed under ventricular tachycardia–flutter–fibrillation

PREMATURE BEATS

Premature beats or extrasystoles are cardiac contractions of ectopic origin which occur earlier than expected in the dominant or usual rhythm [15] The activating impulse may be in a ventricular focus (causing *ventricular premature beats*), or above the bifurcation of the bundle of His (causing *supraventricular premature beats*) Supraventricular premature beats may arise in the atrioventricular node (nodal premature beats), elsewhere in the atria (atrial premature beats), or rarely in the 'tail' of the s-a node instead of normally in its "head" (sinoatrial premature beats) [30]

Premature beats form the commonest of the cardiac arrhythmias and ventricular premature beats occur much more commonly than those arising in the a v node or elsewhere in the atria

The premature beats may occur irregularly and in isolated fashion or they may occur regularly with respect to each other and to the normal beats When irregularities recur in regular fashion they are termed allorhythms When a normal beat followed by an extrasystole recurs seriatim we term the rhythm *bigemini* or *coupling* Coupling is induced by two beats in close proximity followed by a relatively longer 'compensatory' pause The commonest type of coupling is due to alternate extrasystoles and often caused by digitalis [70] Bigemini may also result from partial a v block (p 385) in which every third beat is dropped from sinus pauses every third beat and from 3 2 sinoatrial block (p 383) (For a detailed discussion see Parsonnet et al)[83] In similar fashion trigemini denotes a grouping of beats in threes formed either by a normal beat and two successive premature beats or by two normal beats followed by one premature beat Similar rhythms may result from partial heart block in which every fourth beat is blocked sinus pauses every fourth beat, and 4 3 sinoatrial block It is essential that these rhythms be checked by listening at the apex of the heart, because premature beats may be too weak to produce a palpable pulse at the wrist

Mechanism of Premature Beats

Premature beats are believed to arise when an ectopic focus in the heart becomes so irritable that its rate of impulse formation exceeds that of the sinus node The impulse arising in the ectopic focus spreads radially in all directions and activates the atria or ventricles This concept explains the experimental production of extrasystoles by direct electrical, chemical thermal or mechanical stimulation of local portions of the heart Similar artificial stimuli have been utilized to evoke premature beats in the human heart exposed during operation [3] Stimulation of the vagus and sympathetic nerves has induced extrasystoles in dogs [68] There is also evidence that the higher centers such as the hypothalamus and possibly the cortex control the spinal sympathetic accelerator centers, stimulation of the posterior hypothalamus has elicited premature beats in cats [10] Premature beats in animals observed during chloroform and other types of anesthesia are probably mediated through sympathetic nerves Certain drugs such as digitalis, epinephrine ephedrine and barium chloride can evoke extrasystoles probably directly by increasing neuromuscular irritability as well as indirectly by stimulating the autonomic nerves to the heart Reduction in extracellular or intracellular potassium predisposes to premature beats especially in patients receiving digitalis therapy (p 267)

Several theories have been proposed to explain the exact mechanism by which extrasystoles arise

1 One of these assumes that a single irritable focus in the heart muscle (or multiple foci) develops emits rhythmic stimuli with greater frequency than the normal pacemaker, and occasionally frequently or continuously gains domination of the cardiac rhythm [48] Whenever this new pacemaker can release an impulse which finds the heart muscle not refractory, it produces a premature beat

2 The fact that premature beats often follow the preceding normal beat at exactly identical intervals suggests that the normal contraction in some way controls the ectopic beat which follows De Boer[8] suggested the theory of reentry to explain this exact coupling According to this concept the sinus impulse activates the heart and causes a cardiac contraction, then reenters the ex

citable ectopic focus of heart muscle by an aberrant pathway and elicits another contraction when the heart muscle is no longer refractory. The coupled extrasystole often occurs during the U wave of the preceding beat, at which time there is a supernormal phase of irritability which would favor the initiation of a premature beat. This might explain the constant time relationship between the extrasystole and preceding beat. Fluctuations in pH are important in predisposing to extrasystoles, perhaps by the effect of the former on the supernormal phase of recovery. The temporary diminution or abolition of extrasystoles and other arrhythmias by hyperventilation may be due to induced alkalosis.[75] According to experimental observations of de Boer[9] on the frog's heart, the mechanism responsible for premature beats, like that causing atrial flutter and fibrillation, is not that of rhythmic impulses from a punctate focus but the reentry of an impulse into a circus ring of muscle tissue (p. 351). This theory could explain the cases of bigeminy due to ventricular premature beats, e.g., those due to digitalis intoxication, in which there is usually a fixed coupling in time relationship between normal and premature beats.[69]

3. A third theory, based on the observations of Kaufmann and Rothberger[35] is that of *pararrhythmia* or *parasystole*.[9] According to their concept, abnormal beats (parasystoles) result from the interaction of two foci concurrently initiating impulses at different rates. As a rule, one of these is the normal pacemaker, the sinus node. The other or ectopic focus is responsible for an independent rhythm prevailing side by side (para) with the sinus rhythm. This ectopic site does not respond to the sinus impulse but continues to form its own stimuli which effect a ventricular response whenever the ectopic stimulus falls outside of the refractory period. These rhythms work independently of each other and the sinus and parasystolic beats bear no constant time relationship to each other, unlike the two rhythms in interference dissociation (p. 330) or in many types of extrasystoles in which the sinus and ectopic beats are coupled at fixed intervals.

The parasystolic focus emits impulses which are characterized by absolute regularity, the cycles of which vary less than 0.01 second, in contrast with the sinus impulses which are more variable. In paroxysmal tachycardia (p. 344), which is explained by a similar mechanism, the absolute equality of cycles between beats is apparent. But Kaufmann and Rothberger[35] also showed that if extrasystoles precede or follow a paroxysm of tachycardia, the interval between such isolated extrasystoles is a mathematically exact multiple of the interval between beats of the tachycardia. Of course, many of the ectopic impulses are ineffective because of the refractory state of the muscle which has just responded to a normal sinus impulse. Local blocks to the dominant sinus impulse (entrance block) are assumed to protect the ectopic center and its impulses from being inactivated.[38] Rarely, the rate of impulse formation in the ectopic focus is more rapid than in the sinus node; in such instances some of the outgoing ectopic impulses are blocked from interfering with the sinus impulses (exit block).

In an analysis of ventricular premature beats which gave rise to temporary bigeminal rhythm, Langendorf and associates[48] divided such bigeminy into two major groups. The first consisted of ectopic beats with *fixed coupling* during grossly irregular dominant rhythm, e.g., atrial fibrillation. In this group the extrasystoles occur when the ventricular cycles are long, whereas short cycles tend to preclude their occurrence. This was explained on the basis of a reentry mechanism of the premature systoles. The second group[45] consisted of ectopic beats with *varying coupling* during a regular dominant rhythm. This was explained by either parasystole or reentry, and the intermittency of the bigeminy was attributed to simple interference or to a disturbance in conduction of a parasystolic or of a reentrant impulse. Miller and Antonius[66] described a case of unusual bigeminal ventricular rhythm in the presence of atrial fibrillation with complete atrioventricular block. The ventricular rhythm was controlled by two ventricular foci alternately producing sequences of an extrasystolic and automatic beat.

It is probable that the premature beats or extrasystoles which are so termed on the basis of their clinical and electrocardiographic features are not all due to the same cause. In particular, a distinction must be made between those extrasystoles which bear a fixed time relationship to the preceding beat and those which are independent of the

basic rhythm The former are probably released by an extraneous stimulus reaching an irritable focus rather than by stimuli originating independently at the ectopic focus [illegible] *Those extrasystoles which bear no constant time relationship to the sinus rhythm but which recur with unchanging rhythm, are best explained by the theory of parasystole*

The Electrocardiogram in Premature Beats

The electrocardiogram differs with regard to atrial, atrioventricular or nodal and ventricular premature beats

Atrial Premature Beats An atrial complex and a ventricular complex occur earlier than anticipated (Fig 68) The P wave is usually abnormal in conformation because the origin and course taken by the ectopic impulse are different from the normal However the P wave is always present although difficult at times to identify When the ectopic impulse arises very close to the sinoatrial node or in its "tail" the P wave is similar in appearance is very far from the sinoatrial node or if the premature beat occurs very early in the atrial recovery period before complete recovery from the preceding atrial contraction

The *QRST* complex appears virtually normal, i e similar to the QRS of the basic rhythm in the same lead For after the ectopic impulse has traversed the atrium, its course in the conduction system of the ventricle is identical with that of a normal sinus impulse However although the QRS *of an atrial extrasystole resembles the normal,* its amplitude is often altered and its conformation is slightly different (aberration of the QRS complex), perhaps due to a slight disturbance in bundle branch conduction or slight refractoriness of the ventricular muscle Sometimes the QRS is so altered (slurred notched and widened) that it resembles that of a ventricular premature beat The aberration often manifests itself only in one bundle usually the right, causing the configuration of

Fig 68 Premature atrial beats A woman aged 47 without organic heart disease Lead I Second ventricular complex is a nodal extrasystole with inverted P following RS. Fourth ventricular complex is an atrial premature beat with a compensatory pause Note coupling effect or bigeminy

to the normal P of the basic rhythm and its direction is the same in each lead as the normal P wave When the ectopic impulse arises low in the atrium its direction is usually retrograde toward the s a node In this circumstance P_2 and P_3 are inverted because the direction of the atrial depolarization process is opposite to the normal as it affects leads II and III However P_1 may be upright isoelectric or inverted depending on the degree *to which the ectopic impulse conforms to the* normal right to left direction (of the sinus impulse) Sometimes premature beats briefly separated in time arise from different ectopic foci in the atria (multifocal atrial premature beats) This occurrence is betrayed by differences in form and direction of premature P waves in the same lead

The *P R interval* is usually greater than the minimal normal of 0 12 second because the path of the ectopic impulse to the ventricle is at least as long as that of the normal sinus impulse The P-R interval of the ectopic beat may be abnormally long if the ectopic center a right bundle branch block Refractoriness of the bundle may be physiologic or due to underlying cardiac disease If physiologic the aberrant conduction disappears with increase of the cardiac rate by exercise [9] The height of the T wave may also be altered The degree of prematurity of the atrial premature systole is probably the major factor determining the degree of aberration of the QRS [8] Rarely also the ectopic atrial stimulus occurs so early that *it cannot be transmitted through the a v node* and bundle which are completely refractory or it reaches a refractory ventricular muscle Then the electrocardiogram of the atrial premature beat discloses an abnormal P wave without a following QRS complex This is termed a *blocked premature atrial beat* It differs from heart block in that the P wave occurs prematurely and is usually different in configuration and direction from the P wave of the basic rhythm

The QRST complex of an atrial premature beat is followed by a pause which is slightly longer than the basic T P interval This pro-

longation represents the normal interval between beats plus the interval consumed by the ectopic impulse to travel back to the sino-atrial node. If the P-P interval from the ectopic to the following normal beat is added to the P-P interval between the ectopic and preceding normal beat, it is somewhat less than two normal P-P intervals of the basic rhythm. Thus the T-P pause is longer than normal but not compensatory, i.e., it does not quite restore the dominant rhythm by exactly compensating for the abnormally short T-P interval before the premature beat.

Atrioventricular Nodal or Junctional Premature Beats. The QRS complex occurs prematurely but is usually normal in configuration (supraventricular type), since the nodal impulse follows the normal pathways as it activates the ventricles.

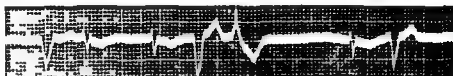
The origin of the premature beat in the a-v node or bundle is indicated by the abnormal position or configuration of the P wave (Fig. 68). The P wave represents either (a) retrograde activation of the atrium by the nodal impulse or (b) normal sinus activation of the atria while the nodal impulse activates the ventricles. In the former circumstance, the P wave is altered in configuration and either precedes, coincides with, or follows the QRS. The ectopic P wave is sharply inverted (V-shaped) in leads II, III and aV_F and upright in aV_R and aV_L. If the atria are activated by the sinus impulse, the P wave is normal in appearance, continues its basic rhythm and may be detected just before, within or after the QRS complex.

With retrograde conduction of the nodal impulse, the P-R interval is less than 0.12 second when it precedes the QRS complex because the pathway from the a-v node to the ventricles is shorter than from the s-a node. The P wave of the nodal extrasystole precedes the QRS when the ectopic focus is in the upper portion of the a-v node, is lost in the QRS when the focus is lower in the node, and follows the QRS when the ectopic focus is in the lowest portion of the a-v node.

Ventricular Premature Beats. The *QRST complex* differs strikingly from the normal because the ectopic impulse takes an abnormal and longer course through the ventricles (Fig. 69A). The QRS is of high voltage, slurred, notched and widened to 0.13 second or more. The T wave is altered secondarily. It is usually directed opposite to the QRS, and is wide and tall. Often the T wave is deformed by a P wave. The P wave, although present, is usually partially or completely obscured by the QRST complex. The ventricular premature beat is distinguished from supraventricular premature beats by the bizarre contour of the QRST complexes and by the absence of premature ectopic P waves. The occasional supraventricular premature beat with bizarre QRST (supra) is associated with an ectopic P wave which is usually very premature.

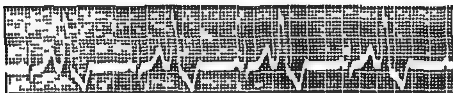
The ventricular extrasystole is followed by an abnormally long pause (T-P interval) preceding the subsequent normal sinus beat. Usually, the ectopic ventricular impulse is not conducted retrograde to the atria and the latter are activated at their normal time by the sinus impulse. Since the dominant sino-atrial rhythm is undisturbed, the normal P and QRS which follow the extrasystole also fall at their expected time. The pause after the extrasystole is therefore really compensatory (Fig. 69B). And the P-P interval between the normal beat preceding and the normal beat following the extrasystole is exactly twice the P-P interval between uninterrupted normal beats. Slight variations may be due to sinus arrhythmia. The T wave in sinus beats following ventricular extrasystoles may be inverted although other sinus beats have an upright T wave. Mann and Burchell[4] found heart disease present in 93 per cent of 46 patients who had inverted T waves following extrasystoles, whereas in a control group in which the post-extrasystolic T wave was upright, heart disease was present in only 57 per cent of cases.

Occasionally, however, the ectopic ventricular impulse is conducted retrograde and activates the atria as well as the ventricles. According to the studies of Kistin and Landowne[44] with esophageal electrocardiograms, such retrograde conduction is common and was demonstrated in 15 of 33 unselected individuals with ventricular premature beats. Retrograde conduction may be documented electrocardiographically by inverted P waves in leads II and aV_F following the bizarre QRS of the ventricular extrasystole. Occasionally a fusion P wave occurs when a retrograde ventricular impulse combines with an antegrade sinus impulse to activate the atria.



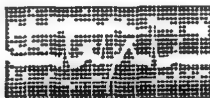
Site of Origin of Ventricular Premature Beats. The electrocardiogram permits a differentiation between premature beats arising

in the left or right ventricles and probably also between those arising at the apex base or near the septum These distinctions are based on electrocardiographic records made while ventricular premature beats were induced by electrical stimulation of human hearts exposed during operations for pericarditis



It is now generally believed that the electrocardiographic configuration of left and right ventricular extrasystoles is exactly opposite to that formerly depicted on the basis of experi-

Apical ventricular extrasystoles are usually characterized by bizarre QRS complexes with main deflection downward in all three leads



Septal ventricular extrasystoles are characterized by QRS complexes which hardly differ from the normal because the ectopic impulse, like supraventricular impulses, reaches both ventricles almost simultaneously The QRS may be slurred, notched and of very low voltage in lead I

mental observations in dogs[49, 69] (See also discussion under bundle branch block p 397) *Right ventricular extrasystoles* are characterized by slurred notched and widened QRS complexes with the main deflection (i e the deflection of greatest duration) upward in lead I and usually downward in lead III Conversely *left ventricular extrasystoles* have the main deflection of the bizarre QRS complex downward in lead I and usually upward in lead III

Basal ventricular extrasystoles are usually characterized by bizarre QRS complexes with main deflection upward in all three leads

It should be noted that the localization of various premature beats may not correspond to the above description when the extrasystoles arise near the dividing line between the left and right ventricles and between base and apex The position of the heart in the chest wall may modify the electrocardiographic conformation of right and left ventricular extrasystoles[44, 49]

When premature beats in a given electrocardiographic lead are seen to arise from different sites as indicated by the direction of the QRS complex they are termed multifocal extrasystoles or bidirectional extra

systoles They are often indicative of digitalis intoxication or of severe myocardial disease

Interpolated Premature Beats The term extrasystole used synonymously with premature beat is misleading in that there is actually no extra beat, the precocity of the premature beat being compensated by the subsequent pause before the next normal sinus controlled ventricular contraction The premature ventricular contraction merely takes the place of a normal sinus ventricular contraction which fail to appear because the ventricles are refractory But occasionally when the heart rate is slow, a premature beat may occur so early in diastole that it is completed in time to permit the next sinus impulse to elicit a ventricular contraction Here the premature beat is added between two normal beats in their normal rhythm and is actually an *interpolated extrasystole* (Fig 69C) The normal beat after the extrasystole may be slightly delayed and its P R interval prolonged due to a partially refractory state of the conduction system The normal beat after the interpolated extrasystole is usually a small contraction due to incomplete filling in the brief diastole between the extrasystole and following contraction The extrasystole itself produces no pulse wave because it occurs so early in diastole that ventricular filling is minimal

Etiology of Premature Beats

The clinical causes of premature beats are uncertain as there is no direct evidence of mechanisms identical with those which induce extrasystoles in the experimental animal (p 332) It is probable that premature beats in man may follow stimuli which reflexly stimulate the vagus and sympathetic nerves e g the premature beats occasionally induced by painful stimuli carotid sinus pressure breath holding or forced respiration and perhaps others of less certain origin

In clinical practice the majority of patients with premature beats are not found to have organic heart disease [30] ■ On the other hand the presence of heart disease has a distinct tendency to increase the occurrence and frequency of premature beats Atrial premature beats tend to occur in association with disease or enlargement of the atria e g in cases of mitral stenosis or cor pulmonale In noncardiac patients premature beats usually appear without apparent cause but they sometimes seem to be related to emotional stress and conflict [81] mental or physical fatigue irregular sleep and digestive disturbances especially when these are combined with excessive smoking or drinking of alcohol or coffee But the relationship is obscure in that only certain individuals are susceptible to premature beats when exposed to the above factors and the same individual does not always respond with premature beats to apparently identical stimuli

Premature beats have been noted in patients with biliary and renal colic as well as with chronic disease of the biliary tract A causal relationship is unproven Infections of various types especially when associated with fever have been said to favor the development of premature beats but without strong evidence Premature beats have been recorded as being related to cerebral lesions ■ Atrial and ventricular premature beats occur with very high frequency during cardiac surgery as a result of manipulation of the heart or neighboring structures and during cardiac catheterization [3, 83, 28, 11] The occurrence of premature beats is so frequent that a causal relationship to any given factor is often difficult to prove or exclude

Age Premature beats occur at all ages but rarely in infancy and childhood They have been heard during auscultation of the fetal heart sounds and confirmed by electrocardiograms taken immediately after birth After the age of 50 the frequency increases notably and after 70 premature beats occur intermittently in almost all individuals

Symptoms of Premature Beats

Most persons with premature beats are unaware of their presence But often there is a momentary, more or less disturbing local discomfort in the precordium The greatest discomfort has usually been attributed to the long compensatory pause after the premature beat or to the strong contraction that follows But Kline and Bidder[42] demonstrated that the disagreeable sensation was due to the premature beat or the compensatory pause and Ungerleider and Gubner[81] indicted the *premature beat* alone as the cause of discomfort

There may be a sensation of stoppage of the heart momentary faintness or dizziness and intense associated anxiety The normal beat after the premature contraction is experienced as a strong thump against the chest wall as the ventricle expels its unusually large content accumulated during the long diastolic

pause The entire sequence of extrasystole, long pause and strong beat produces an irregularity which evokes a distressing heart consciousness or palpitation which may be described as an oppression, fluttering thumping skipped beats, or a sinking feeling Occasionally the discomfort is localized in or radiates to the neck where the patient experiences a fullness, tightness pulsation or *wave reaching to the top of the head This* may be caused by the regurgitant stream from the right atrium to the neck veins when the atrium contracts simultaneously with the ventricle and the tricuspid valve is shut

When runs of extrasystoles occur, general symptoms such as anxiety pallor, sweating nausea, weakness dizziness faintness and breathlessness may ensue It is often difficult to determine to what extent these symptoms are of psychic or of circulatory origin There may be distinct pain simulating that of angina pectoris

Premature beats often become annoying when the patient is at rest and apparently relaxing especially when he retires for the night It is uncertain whether slowing of the heart rate at such times predisposes to their appearance or whether the absence of other distractions makes the patient more aware of their *existence Conversely exercise often seems to* eliminate the premature beats In fact they are often eliminated at least temporarily by any factor which increases the heart rate e g exercise atropine, nitrites In some patients however especially in patients with organic heart disease premature beats are induced by exercise

Physical Signs of Premature Beats

Auscultation of the heart detects the premature beat which occurs too early in the cardiac cycle and is followed by a longer pause than normal The premature beat may be similarly recognized at the pulse but often the premature contraction is too weak to produce a palpable pulse wave

Both sounds of the premature contraction are usually audible but only the first sound may be heard if the ventricular contraction is too slight to open the semilunar valves The extrasystolic heart sounds may be dull and almost inaudible if the ventricle contracts when it is very incompletely filled or more often there may be a sharp snapping first sound By a simultaneous phonocardiographic and electrocardiographic study, Cossio et al[14] found that in 15 of 16 patients with atrial extrasystoles, the first sound of the extrasystole was always louder than the first sound of the preceding or following normal systole In cases of ventricular premature beats, the first sound was usually louder but occasionally of normal or diminished intensity When the first sound of the extrasystole was louder it *was also delayed in onset relative to the onset of the QRS The increased intensity and de*layed onset depend on the degree of prematurity and the consequent position of the a v cusps With premature contractions the a v cusps are lower than normal at the onset of ventricular contraction More time therefore elapses before the valve is closed and this is associated with increased motion increased vibration and increased intensity of sound Splitting of the first sound is due to asynchronous contraction of the ventricles which occurs only with ventricular premature beats This asynchronism accounts also for the lower incidence of intensified first sounds with ventricular extrasystoles

Diagnosis

Premature beats are usually recognized easily by auscultation and less regularly by palpation of the radial pulse Sometimes they *occur so infrequently* that they are absent at the time of physical or electrocardiographic examination but their occurrence may be suspected from the patient s description

The electrocardiogram is essential for definite diagnosis and localization of premature beats (p 334) Ventricular extrasystoles are usually distinguishable from atrial or *nodal extrasystoles by the widening notch*ing and slurring of the QRS in the former and the relatively normal QRS complex in the latter two The P wave in atrial premature beats precedes the QRS the P R interval is normal and the T P pause is longer than normal but not compensatory The P wave in nodal premature beats is inverted in leads II and III may follow be fused with or precede the QRS complex But if it precedes then the P R interval is abbreviated to less than 0 12 second Rarely upright P waves in leads II and III were observed in a case of lower a v rhythm[15]

Clinical differentiation between atrial nodal and ventricular premature beats is extremely difficult but may be successful

based on the following observations Ventricular extrasystoles are followed by a compensatory pause which permits the next beat to occur at the same time as if there had been no premature beat On the other hand the pause after an atrial extrasystole is incomplete and the following normal beat occurs too early in the basic rhythm as may be determined by meticulously and rhythmically counting and tapping with a pencil or with the foot A striking systolic a pulsation in the neck may accompany a nodal or ventricular extrasystole instead of the normal systolic collapse since the atrium may contract at the same time that the tricuspid is closed by the nodal or ventricular extrasystole Interpolated extrasystoles may be suggested by the occurrence of three beats in rapid succession in the time normally occupied by two and without a long pause In trigeminy three beats in rapid succession are followed by a long pause

When multiple premature beats recur frequently they may be confused with atrial fibrillation on clinical examination The rate of the latter is usually rapid (120 or more) unless the patient has been digitalized Increase of the heart rate by exercise or the administration of nitrites will often eliminate the extrasystoles but not atrial fibrillation Careful auscultation discloses that the long pauses in extrasystoles are preceded by a premature beat with atrial fibrillation there are pauses without preceding premature beats The electrocardiographic distinction is simple

Extrasystolic bigeminy may be distinguished from cardiac alternans (p 146) by auscultation which reveals even spacing in time in alternans while there are briefer and longer intervals in bigeminy

Sinus arrhythmia and heart block may produce an irregularity resembling frequent premature beats Electrocardiographic study is desirable for differentiation Careful auscultation discloses that the irregularity in sinus arrhythmia is one of increasing and diminishing frequency of beats often related to the phases of respiration and may be abolished by exercise (p 325) In heart block there is usually a bradycardia and the irregularity is not characterized by premature beats which are always followed by a long pause

Prognosis

As a rule premature beats are of no clinical importance They appear in isolated fashion at infrequent intervals and produce minimal momentary symptoms or none at all They are usually unaccompanied by organic heart disease When heart disease is present its diagnosis and prognosis should be based on findings independent of the extrasystoles According to Berliner and Huppert[4] benign ventricular premature systoles are associated with a narrower QRS than those accompanying organic heart disease extrasystoles with a QRS wider than 0 16 second were considered to suggest the probability of organic heart disease The presence of premature beats per se without associated heart disease rarely has significance as to longevity or as to suitability for life insurance military service or employability Occasionally the frequency of the extrasystoles or the anxiety associated with their occurrence produces symptoms of a severity out of proportion to their prognostic unimportance

Atrial premature beats may be clinically more important because of the greater likelihood of underlying heart disease Their presence should initiate an especially careful search for rheumatic heart disease with mitral stenosis In patients known to have mitral stenosis they may represent harbingers of impending atrial tachycardia flutter or fibrillation However even atrial premature beats are not of serious prognostic significance when there is no underlying heart disease

Ventricular premature beats are often of serious import when they are multifocal i e when they come from several different sites in both ventricles as seen in a given lead of the electrocardiogram This finding may denote advanced myocardial disease and impending ventricular tachycardia or fibrillation But it may also be indicative of reversible myocardial irritation due to digitalis intoxication Extrasystoles forming bigeminal rhythm are commonly due to digitalis intoxication When they occur with small doses of digitalis they are said to imply an unfavorable course

TREATMENT

General Measures

Premature beats are usually asymptomatic and require no treatment When as is often the case the extrasystoles are first discovered on routine examination and are unknown to the patient attention should not be directed to their presence However in ex

ceptional circumstances it may be preferable to state their presence and explain their insignificance if it is likely that the patient will see some other physician who may alarm him. If the patient is aware of their occurrence no treatment is usually necessary except convincing the patient that he has no heart disease. In the absence of heart disease the patient may receive special encouragement if he is told that none of his activities need be restricted. Whether or not heart disease is associated, the patient sometimes needs assurance that nothing dire will eventuate.

Treatment is indicated when the symptoms due to the extrasystoles are distressing despite reassurance. Possible irregularities in hygiene should be corrected even if no definite causal relationship can be proven. The patient should obtain adequate sleep and sufficient periods of both relaxation and simple exercise. Constipation should be corrected. The diet should consist of bland, easily digestible foods and the caloric intake should be diminished if the patient is obese and has been gaining weight. A cholecystectomy or dietary correction of symptoms due to disease of the biliary tract or peptic ulcer may be followed by disappearance of the premature beats. Emotional stresses should be eliminated if possible. Sometimes a vacation with change of environment may be necessary and helpful. Sedatives such as phenobarbital, chloral hydrate or bromides may be beneficial.

Aside from these general measures, it is advisable to eliminate smoking, alcohol and coffee completely at least for a reasonable test period. If the premature beats disappear or become tolerable, resumption in moderation may be tried if desired. When premature beats occur in bigeminal or multifocal form during digitalis therapy, digitalis should be discontinued.

Specific Drug Treatment

The most effective specifically antiarrhythmic drugs in the treatment of premature beats are procaine amide (chiefly for ventricular extrasystoles), quinidine and potassium salts (chiefly in digitalis induced extrasystoles). Occasionally digitalis abolishes premature beats.

Procaine Amide (Pronestyl). Procaine amide has been found to be effective in the treatment of various cardiac arrhythmias especially ventricular premature beats and ventricular tachycardia.[39, 46, 59, 83] In my experience it is more effective than quinidine in the prevention and treatment of ventricular premature beats.

Procaine amide differs structurally from procaine in that para aminobenzoic acid and diethylaminoethanol are bound through an amide (NH) linkage instead of an ester linkage as in procaine. It is not affected by the procaine esterase of the body and is therefore more stable. Hence therapeutic levels can be readily maintained. It is effective by the oral route as well as by intramuscular or intravenous injection. It produces much less central nervous stimulation than procaine.

Myocardial Action. Procaine amide acts, like quinidine, by depressing myocardial excitability.[65] It is presumed to raise the ventricular threshold to stimulation, to prolong ventricular conduction and possibly to increase its refractory period. It has a similar action on atrial muscle but to a lesser degree. Hemodynamic studies[64] indicate that procaine amide reduces the cardiac output and the pulmonary artery pressure and slows the velocity of the blood flow.

Administration and Dosage. To abolish and prevent the recurrence of premature beats Pronestyl is given orally in an initial dose of 0.75 to 1.25 gm. followed by 0.5 gm. (2 capsules each 250 mg.) at four to six hour intervals, i.e. four to six times daily. When the extrasystoles are controlled the dose is progressively reduced to 0.5 gm. four times daily or three times daily. Finally a maintenance dose of 0.25 gm. four times daily is usually adequate. If this initial schedule is ineffective, 1 gm. doses may be given at four hour intervals until the extrasystoles are controlled or there are toxic symptoms. Usually a peak plasma level is attained with this dose in one hour and this level declines to minimal levels in four to six hours. Thus a cumulative effect is obtained when the drug is administered in doses of 0.5 to 1.0 gm. at four hour intervals or oftener, and frequently also when administered at six hour intervals.

Because of possible toxicity of Pronestyl patients taking the drug over a continuous period of time must be checked by repeated blood counts and electrocardiograms.

Toxic Effects. *Electrocardiographic changes* may occur similar to those produced by

quinidine *Widening of the QRS complexes* is a characteristic toxic effect Caution is indicated when the QRS complexes are prolonged beyond 0 14 second *Ventricular tachycardia* is occasionally induced and rarely ventricular flutter or fibrillation [13, 19, 25] Less striking electrocardiographic changes not necessarily toxic include prolongation of the Q T interval diminished voltage of the QRS complexes lowering or inversion of the T wave, slight prolongation of the P R interval and electrical alternans

Gastrointestinal symptoms especially anorexia nausea or vomiting are not uncommon But these are likely to occur only with larger doses such as 4 gm or more daily These symptoms rarely require discontinuation of the drug except temporarily As a rule the symptoms will not reappear if smaller doses of the drug are resumed

Agranulocytosis is very uncommon but one of the most serious complications and has been fatal in some cases [33] Usually it occurs after prolonged oral medication

Hypotension is a serious complication of Pronestyl only when the drug is administered intravenously [30, 4] Hypotensive effects after intramuscular or oral administration are infrequent and insignificant [2] Following intravenous administration some degree of hypotension is common depending in part on the dose and speed of administration Fatalities due to shock myocardial ischemia or other reactions may occur especially in patients with severe myocardial disease [4]

Other toxic effects which are relatively rare include headache drowsiness mental symptoms or psychoses urticaria chills and fever [1] or profuse sweating

Quinidine Sulfate (See also p 365) This acts by depressing myocardial excitability One may begin with an initial test dose of 0 2 gm (3 grains) followed by 0 3 to 0 6 gm (4½ to 9 grains) three to six times daily for a trial period of a week If desired these dosages may be attained by progressive increases If the extrasystoles disappear a maintenance dose may be determined by gradual reduction of the dose Eventually it should be discontinued Sometimes digitalis in doses of 0 1 gm three times daily for three days followed by 0 1 gm daily is effective whether or not heart failure is present and even when quinidine has failed

Potassium Salts Potassium chloride phosphate or acetate is often effective in controlling extrasystoles especially those due to digitalis toxicity [11, 7] The dosage is 2 to 4 gm (30 to 60 grains) three or four times daily dissolved in a 25 per cent solution and suitably flavored [7] or it may be given in tablet form For intravenous administration potassium is available in ampules containing 3 7 gm or 50 mEq of potassium chloride The contents are dissolved in 500 or 1000 cc of 5 per cent glucose in distilled water and administered by intravenous drip in not less than 2 hours Stronger concentrations or more rapid flow usually results in almost intolerable pain along the vein *Potassium salts are contraindicated or should be given with the greatest caution in patients with serious renal impairment*

Magnesium salts have also been found effective in abolishing extrasystolic bigeminy due to digitalis [6, 21] Benemid (Probenecid) administration was followed by disappearance of disabling bigeminal extrasystoles in a case of gout [6] It was presumed that the Benemid abolished an ectopic ventricular focus due to uric acid deposit by increasing the excretion of uric acid

Ambonestyl (2 diethylaminoethyl isonicotinamide) Preliminary reports indicate that this drug administered intravenously in 0 5 gm doses at 10 minute intervals suppresses premature ventricular contractions and bigeminal rhythm [13] It appears to have advantages over procaine amide and quinidine in the absence of depression of cardiac conduction and lack of serious hypotension on intravenous administration These advantages suggested that Ambonestyl might be particularly useful in treating ventricular arrhythmias in patients with conduction disturbances in controlling arrhythmias during anaesthesia and cardiac surgery

Chapter 14

THE ECTOPIC TACHYCARDIAS

The ectopic tachycardias denote abnormally rapid cardiac rhythms in response to impulses arising outside the sinoatrial node. They are also termed paroxysmal tachycardias because of their frequent occurrence as attacks of cardiac acceleration which start and stop abruptly. They include

1. Atrial (and nodal) paroxysmal tachycardia
2. Atrial flutter
3. Atrial fibrillation
4. Ventricular tachycardia
5. Ventricular fibrillation

Like premature beats these tachycardias are engendered by stimuli which arise in ectopic centers in the atria or ventricles, they are therefore classified as ectopic rhythms. They are distinguished in this respect from sinus tachycardia in which the rate is also rapid but the controlling impulse arises normally in the sinoatrial node. The ectopic focus responsible for premature beats dominates the rhythm of the heart intermittently while that responsible for paroxysmal tachycardia becomes the pacemaker for shorter or longer continuous periods.

The paroxysmal tachycardias are considered separately because it is the rapid heart rate more than any other feature of a cardiac arrhythmia which produces serious circulatory disturbances. As a rule the arrhythmias hardly derange circulatory function and provoke little local precordial discomfort provided the heart rate is slow or normal. Bradycardias, even of intense degree whether regular or irregular are also rarely responsible for circulatory distress unless the interval between beats exceeds 3 seconds. Within a reasonable range a satisfactory circulation is maintained regardless of rate or rhythm, provided there is an adequate interval for myocardial recovery and ventricular (diastolic) filling. On the other hand these essential events become progressively restricted with increasing cardiac rate (p 91).

Ordinarily paroxysmal tachycardias are transient while the dominant rhythm is of sinus origin and the rate is normal. Sometimes runs of atrial, nodal or ventricular systoles termed *repetitive paroxysmal tachycardia*[153, 47] are almost constantly present for months or years and thus become the dominant rhythm while normal sinus rhythm interrupts only transiently. Such paroxysms consist chiefly of atrial tachycardia less commonly of ventricular tachycardia, but also of nodal tachycardia, atrial flutter or fibrillation. Organic heart disease is usually absent. Palpitation, independent of exertion dyspnea and syncopal attacks are the commonest symptoms. The prognosis is good and the paroxysms in children disappear during adolescence. Those in adults tend to subside spontaneously. Drug treatment is usually ineffective.

Rare cases of *chronic atrial tachycardia*[47] have been distinguished from repetitive atrial tachycardia by the absence of periods of sinus rhythm in the former. Chronic atrial tachycardia may be associated with varying degrees of atrioventricular block and a ventricular rate between 120 and 180 per minute. This arrhythmia is refractory to treatment but digitalis is useful to slow the ventricular rate.

ATRIAL PAROXYSMAL TACHYCARDIA

This is the common form of recurrent palpitation associated with very rapid but extremely regular heart rates.[113] Atrial paroxysmal tachycardia is observed many times as frequently as ventricular tachycardia. A distinction between paroxysmal tachycardias initiated in the a v node and those initiated elsewhere in the atria is often extremely difficult or impossible.

Mechanism

It has been assumed that atrial paroxysmal tachycardia like atrial extrasystoles results from a rapid succession of rhythmic impulses arising in an irritable ectopic focus in the

atrium[1,7] Transitions from atrial extrasystoles to atrial tachycardia are sometimes seen in the same electrocardiograms and the configuration of the complexes is identical in both arrhythmias The possibility also that this ectopic focus is a parasystolic center protected by local blocks has been suggested by advocates of the theory of parasystole (p 333) More recently the theory of circus rhythms generally invoked to explain atrial flutter and fibrillation (p 351) has been expanded to apply also to atrial paroxysmal tachycardia The evidence for this belief has been summarized by Barker Wilson and Johnston[11] who suggested that atrial paroxysmal tachycardia is due to a special kind of circus rhythm (reentry) which involves the sinoatrial or the atrioventricular node in its pathway But curves of the momentary atrial electrical axes suggest that the atrial tachycardia unlike flutter and fibrillation is not due to circus movements[84] An essential distinction is the separation of the atrial deflections by isoelectric intervals in atrial tachycardia whereas in atrial flutter the electrocardiographic oscillations are continuous and there is no isoelectric interval between P waves But Prinzmetal et al[137] have stressed that the undulatory pattern of atrial flutter is dependent in large measure on the atrial rate and is not present in all leads or in borderline cases and that there is not a fundamental difference between atrial flutter and tachycardia

The atrial rate varies usually between 140 and 220[113] per minute but most commonly between 180 and 200 Occasionally the atrial rate is as high as 300 per minute The ventricles almost always respond to each atrial beat But several series of cases have been collected in which there was an associated atrioventricular block usually 2 1[83] Paroxysmal atrial tachycardia with block has been noted occasionally as a result of digitalis intoxication especially with deficient potassium[70, 134] and in association with posterior myocardial infarction[137] Paroxysmal tachycardia may be associated with bundle branch block and occasionally as a result of digitalis toxicity with bidirectional aberrant ventricular complexes suggesting alternate conduction down the left and right bundle branches [4, 100] In infants atrial paroxysmal tachycardias occur in which the atrial rate is as high as 300 per minute and yet there is a 1 1 ventricular response[107, 205] The usual atrial rate of 140 to 220 in paroxysmal atrial tachycardia compares with an atrial rate of 250 to 350 in atrial flutter and 400 to 600 in atrial fibrillation The progressively greater frequency of a v block in the latter two conditions is explainable by the more frequent atrial impulses attempting to traverse the a v node and bundle and probably also by some impairment in atrioventricular conduction in atrial flutter and fibrillation

The Electrocardiogram

The characteristic feature is a rapid regular series of ventricular complexes (RT waves) with the T wave slightly modified by fusion with the P wave (Fig 70) The QRS complex is usually of relatively normal contour but in prolonged paroxysms especially with ventricular rates exceeding 200 per minute the QRS may become widened notched and slurred due to impaired intraventricular conduction

The P waves though present are difficult to identify because the abbreviated interval between beats causes them to fuse with the preceding T When only QRS complexes are apparent atrial tachycardia cannot be distinguished from nodal tachycardia When identified the P waves in limb leads I and II are usually upright and relatively normal in contour suggesting that the atrial impulse originated in the cephalic portion of the atrium near the sinoatrial node Occasionally the P waves may be inverted in leads II and III suggesting an origin in or near the a v node In nodal tachycardia the P R interval is abbreviated or the P wave is concealed in or follows the QRS complex Paroxysmal nodal tachycardia may be associated with retrograde heart block reciprocal rhythm and blocked reciprocal beats[35] The P waves in atrial tachycardia may be best identified by taking esophageal leads[3, 38] or a precordial lead from the right side of the sternum[46] e g by placing the exploring chest electrode in the third interspace to the right of the sternum[5] In this manner also the occasional occurrence of a v block (usually 2 1) in atrial paroxysmal tachycardia may be discovered[66] Atrial tachycardia with the Wenckebach phenomenon has been observed during the course of cardiac catheterization[1,1] The T wave is often inverted after an attack of paroxysmal atrial tachycardia but rapidly reverts to normal

The onset of a paroxysm as observed in electrocardiograms, commences abruptly with a preliminary extrasystole its termination is likewise abrupt, a brief pause intervening before the prompt resumption of sinus rhythm

Etiology

The etiology of atrial paroxysmal tachycardia is obscure The same nervous, toxic and digestive disturbances, emotional stress fatigue, exertion and disease of the biliary tract which have been held responsible for premature beats, have also been indicted as responsible for attacks of atrial tachycardia Atrial tachycardia occurs frequently in patients with the Wolff Parkinson White syndrome (p 405) Atrial tachycardia, like other atrial arrhythmias has been observed during cardiac catheterization[143 [illegible]] and cardiac surgery[25] Pregnancy was said to predispose to paroxysmal atrial tachycardia[201] Paroxysmal atrial tachycardia with atrioventricular block may be induced by digitalis[70 134] (p 267) Chronic atrial tachycardia, with slowing of the heart rate and occasional sinus rhythm with recumbency only has been reported[145]

Heart disease is usually absent, but evidence of rheumatic cardiovalvular disease is not uncommon Atrial tachycardia is uncommon in myocardial infarction[9]

Paroxysmal atrial tachycardia occurs at any age, possibly it is most common between twenty and forty [illegible] [134] Its occurrence in infancy and childhood has been reviewed by Nadas et al[148] in a study of 41 cases and by Wright[19] Usually it is discovered in the first four months of life and almost always in boys *It may be congenital,*[3] and cases of paroxysmal tachycardia with onset in utero have been described[215] While the paroxysms *of tachycardia in infants and children are* usually atrial tachycardias they are occasionally atrial flutter and rarely ventricular tachycardias Recurrences are probable during the first year of life but usually not thereafter, unless the child has Wolff Parkinson White syndrome In older children paroxysmal tachycardias affect either sex and in the majority of cases are associated with congenital heart disease or some other etiologic factor Rhabdomyoma of the heart has been found at postmortem examination of some infants who had *suffered from paroxysmal* atrial tachycardia[113]

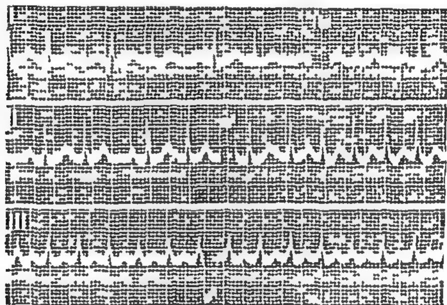

Fig 70 Atrial paroxysmal tachycardia Occasional atrial premature beats in leads I and II preceding onset of atrial tachycardia in lead II and continuing in III Ventricular configuration resembles normal complexes in lead I P and T fused Rate 190 per minute.

Symptoms

The onset is sudden and without warning Often a rapid change in position of the head or trunk an unexpected emotional upset or an unpleasant dream appears to unleash the attack But usually there is no apparent precipitating cause

There may be a sudden thump or two *against the chest wall* a seeming momentary

stoppage of the heart or some other precordial discomfort followed by a continuous palpitation fluttering racing or pumping of the heart beat Sometimes there is definite precordial pain a smothering sensation in the chest and throat fullness or a sense of pulsation in the neck and head or epigastric distress However there may be only mild palpitation or no symptoms at all especially with relatively slow ventricular rates or with paroxysms of brief duration

These *local symptoms* are often overshadowed by *psychic and reflex nervous* manifestations especially when the attacks persist for more than a few minutes Anxiety or even angor animi weakness or exhaustion coldness or sweating and a sense of smothering may occur early There may be dizziness faintness or momentary syncope at the onset Abdominal distention, gaseous eructations salivation nausea or vomiting may occur Occasionally the vomiting appears to terminate the attack whether the emesis occurs spontaneously or is induced There may be polyuria during or at the termination of the paroxysm

Serious circulatory disturbances may develop if the rate is exceedingly rapid but especially if there is underlying cardiac disease and if the paroxysm is prolonged Although physiologic experiments indicate that acceleration of the heart beyond 180 per minute progressively reduces the cardiac output it is remarkable how often heart rates over 200 per minute are tolerated for many hours or even days without evidence of circulatory insufficiency provided the heart is otherwise normal But in hearts with serious organic disease prolonged tachycardia is very likely to induce failure especially pulmonary edema

Weakness pallor perspiration and coldness of the extremities may be due to a diminished cardiac output The clinical picture of shock with extreme hypotension may develop Cerebral ischemia may be responsible for faintness or syncope In extreme degree peripheral slowing of the circulation is followed by thrombosis and gangrene of an extremity

Symptoms and signs of congestive heart failure may also develop These include dyspnea and cough due to left ventricular failure Occasionally there is a frothy blood stained sputum indicative of pulmonary edema The patient s veins may become engorged and his pallor suffused with cyanosis The liver may enlarge and the abdomen become painful and tender The attack may occasionally terminate fatally, either with signs of progressive failure or suddenly As a rule however the paroxysm ends abruptly normal rhythm is restored and the symptoms and signs of circulatory insufficiency abate rapidly

The occurrence of pain has been mentioned Occasionally the pain closely resembles the compressing substernal pain of angina pectoris or cardiac infarction It may actually be due to functional coronary insufficiency and myocardial anoxia secondary to the tachycardia

The *paroxysmal supraventricular tachycardia in infants* is characterized by a cardiac rate of 150 to 300 in one instance 305 per minute[15] Although it may be asymptomatic and is often unrecognized[16] there is usually failure to eat fretfulness or drowsiness vomiting pallor or cyanosis tachypnea fever and leukocytosis Congestive heart failure may result when the tachycardia is prolonged but cases of atrial tachycardia persisting for years with rates of 150 to 200 have been reported without clinical evidence of heart failure[17] In the presence of heart failure cardiac and hepatic enlargement are the prominent findings Pneumonia is often diagnosed instead of heart failure but both pneumonia and heart failure may be present

Signs

Physical examination usually reveals only the regular rapid heart rate The rate remains mathematically constant despite changes of position emotion or exercise[11] The heart sounds may present a tic tac rhythm (embryocardia) The heart is usually normal in all other respects However cardiac enlargement and murmurs may disclose underlying heart disease Sometimes enlargement develops only with the occurrence of heart failure this is reversible with restoration of normal rhythm Murmurs previously present such as that of mitral stenosis may disappear during the tachycardia Therefore examination at that time may not reveal the underlying disease

In severe and prolonged attacks the patient may appear obviously anxious or agitated and there may be objective signs of congestive failure

The pulse is very rapid and small but regular However, since the pulse may be very

deceptive as to regularity or irregularity this quality should always be determined by cardiac auscultation

There may be a prominent and even palpable pulsation of the cervical veins

The blood pressure often falls during severe or long paroxysms Under these circumstances the systolic pressure drops more than the diastolic with a resulting fall in pulse pressure

Diagnosis

See page 378 for diagnosis and differential diagnosis of the tachycardias

Prognosis and Course

Paroxysms of atrial tachycardia stop as abruptly as they begin either spontaneously or because the patient adopts certain positions takes a deep breath holds his breath with glottis closed or because the physician controls the attack As a rule, the attacks subside spontaneously in seconds or minutes, but attacks with disturbing symptoms last for several hours and occasionally for several days They are distinguished from attacks of atrial flutter which may persist for many days weeks or even months (chronic atrial tachycardia)[107] However the attacks of paroxysmal tachycardia which are associated with atrioventricular block often last for many hours or days and occasionally for weeks months or even years[113]

In most cases paroxysmal atrial tachycardia is of no clinical importance either from the viewpoint of producing disturbing symptoms or of denoting the presence of organic heart disease The paroxysms may occur rarely at long intervals or a few times in an entire lifetime Occasionally, however, they recur with some frequency varying from several times a year to several times a week Except in rare instances in which they recur frequently or are very prolonged they neither interfere with gainful work lead to heart failure nor shorten life In some persons attacks of atrial tachycardia foreshadow the development of atrial flutter or fibrillation In cases in which there is associated anatomic heart disease especially in cases of atrial tachycardia with atrioventricular block,[114] prolonged and severe attacks may lead to congestive heart failure,[90] and rarely to peripheral thromboses and gangrene Adams-Stokes syndrome and cardiac infarction without acute coronary occlusion Heart failure may be induced occasionally also in the apparently normal heart

Treatment of Atrial Tachycardia

Treatment is directed at (1) control of the acute attack of atrial tachycardia and (2) prevention of future attacks or diminution of their frequency in persons subject to frequent paroxysms

The Acute Attack The acute attack may sometimes be terminated by the patient if he is instructed to try to sit, leaning forward with his head down to lie prone across the bed with his head lower than his trunk, to take a deep breath with glottis closed after a complete expiration (Muller procedure), or to expire forcibly with glottis closed after a deep inspiration (Valsalva experiment) Sometimes a patient or a member of his family learns to abort the attack by firm (painful) pressure on one eyeball with the eyelid closed (oculocardiac reflex) Induced gagging and vomiting by irritating the pharynx with the finger is occasionally effective Most of the effective therapeutic measures restore sinus rhythm by vagal stimulation,[48] which diminishes the rate of impulse production in the sinoatrial and atrioventricular nodes

Carotid Sinus Stimulation The physician s most useful procedure is to massage the right carotid sinus and if this is ineffective the left carotid sinus for 10 to 30 seconds The carotid sinus may be located by feeling the strong carotid arterial pulsations at the bifurcation of the common carotid at the level of the upper border of the thyroid cartilage The patient should be recumbent with head extended and turned slightly to one side a pillow under the back of the neck Pressure and massage are best performed with two or three fingers compressing the artery and sinus posteriorly and medially against the vertebral spine A massaging motion is preferable to direct pressure lest the artery be compressed below the sinus itself I prefer to listen with my stethoscope or ear against the patient s precordium as I perform the massage In this way unnecessary prolongation of the procedure is avoided with the possible risk of syncope or cardiac standstill Cardiac auscultation is also important because carotid sinus pressure is often useful not only for terminating the attack but also for the differential diagnosis of the various forms of tachycardia (p 378) Attention is directed

to the occasional occurrence of transient or permanent monoplegia[73] or hemiplegia following carotid sinus stimulation.[24]

A similar vagal reflex may be induced by firm pressure over one eyeball at a time and then, if necessary, over both eyeballs simultaneously.

If these mechanical measures fail, a number of drugs may be employed, chiefly for their stimulating effect on the vagus nerve. *Reassurance* and the administration of a *sedative* (e.g., 0.2 gm. pentobarbital sodium) orally or by injection are important preliminary measures to the use of the more specific drugs.

Digitalis administered intravenously [illegible] now widely employed as the drug of choice in the treatment of atrial tachycardia. Cedilanid (lanatoside C) is utilized because of its rapid action and elimination and its lesser hazard than the somewhat swifter acting ouabain.[64, 1] As a rule, the ectopic tachycardia is converted to sinus rhythm without serious toxic symptoms with doses of 4 to [illegible] cc. (0.8 to 1.6 mg.). Weisberger and Feil[98] administered lanatoside C intravenously in a dose of 0.8 mg., repeated in 30 to 60 minutes if necessary. In 16 of 17 instances of paroxysmal tachycardia, the tachycardia stopped suddenly within 40 minutes after the first dose; in the remaining case it stopped within 12 hours. In 26 cases treated by Barrow[1] conversion was effected in all cases within a period of 1½ hours and often within 15 to 30 seconds. The usual dose was 1.2 to 1.6 mg. injected intravenously in 60 to 120 seconds. Digitalization may also be effected rapidly with the oral preparation of digitoxin. In general, full doses of digitalis should be given before discontinuing it as ineffective. (For preparations and methods of administration of digitalis, see p. 259.)

Ouabain (p. 262) is administered if there is great urgency. Acetylstrophanthidin was reported to restore sinus rhythm in 11 of 12 cases of supraventricular tachycardia.[6] But this drug may produce fatal arrhythmias[24, 63] and its use in the treatment of paroxysmal atrial tachycardia is rarely justified, particularly because of the availability of other effective drugs.

Phenylephrine (Neo-synephrine) hydrochloride[9, [illegible]] has taken the place of Mecholyl in my practice because of its equal effectiveness without the unpleasant and often alarming side actions of Mecholyl. I use Neo-synephrine whenever carotid sinus stimulation has failed to restore normal rhythm in paroxysmal atrial tachycardia. Thus far Neo-synephrine has been uniformly successful in my hands, often after many other measures have been tried and the attack has lasted for hours. The drug is believed to act by raising the blood pressure and thereby stimulating carotid sinus and aortic receptors with consequent reflex vagal stimulation.

Neo-synephrine hydrochloride, 1 per cent solution for intravenous use, is employed. I draw up 0.3 cc. in a tuberculin syringe, dilute with sterile saline or distilled water to 1 cc. and inject 0.3 cc. (0.9 mg.) of this rapidly intravenously, holding the needle in the vein. As a rule, sinus rhythm is restored within 60 to 90 seconds or less. If not, I slowly introduce the remainder of the solution intravenously. The drug is either contraindicated or should be given with great caution in patients with organic heart disease, severe hypertension, hyperthyroidism, partial heart block or marked bradycardia. Intense headache and anxiety may occur. Short runs of ventricular tachycardia have been observed following the use of Neo-synephrine in a patient with coronary heart disease and paroxysmal atrial tachycardia.[63] When there is any possible contraindication to Neo-synephrine, I prefer to administer a sedative and utilize Cedilanid intravenously if carotid sinus stimulation has failed.

Methoxamine (*Vasoxyl*) has been found equally effective[100, 18, 40] and possibly other pressor amines may be similarly employed to control paroxysmal atrial tachycardia. Methoxamine is administered intramuscularly or intravenously in a dose of 10 to 20 mg. Its action is similar to that of Neo-synephrine but is said to have the advantage of causing no increase in cardiac irritability. Nausea, weakness, apprehension, agitation and momentary asystole occur very briefly during the transition to sinus rhythm and may be quite upsetting to the patient.

Levarterenol (*Levophed*), 8 to 16 mg. in 1000 cc. of 5 per cent glucose, administered intravenously at the rate of 20 to 40 drops per minute and adjusted to raise the systolic blood pressure rapidly to 120 to 160 mm. Hg, was effective in terminating supraventricular tachycardia in 6 patients.[44]

Mecholyl (acetyl beta methylcholine chlor

ide), 20 mg (⅙ grain) administered hypodermically,[192] is being used less and less often (Fig 71) Unpleasant and sometimes alarming reactions occur, including extreme flushing of the face, perspiration, intense salivation a sense of choking or of imminent death and, rarely, collapse Nausea and vomiting are not uncommon, but usually at or after termination of the attack

Neostigmine injected subcutaneously in doses of 0 5 to 2 mg (1 to 4 cc of a 1 2000 solution) has also been employed in the treatment of supraventricular tachycardia,[203] but alarming reactions have been reported [8]

Pronestyl may also succeed in terminating attacks of atrial tachycardia [9] although it is generally less effective than in the control of ventricular tachycardia Nevertheless Berry and associates [8] established sinus rhythm with procaine amide in 18 of 22 episodes of supraventricular tachycardia, and Pascale et al [154] converted 10 of 13 episodes of paroxysmal supraventricular tachycardia to sinus rhythm It is particularly effective in nodal tachycardia [171] An intramuscular injection of 500 mg may be given and repeated in 2 hours if necessary [15] Or Pronestyl may be given intravenously no faster than 100 mg per minute, up to 1000 mg if necessary (p 375)

Potassium salts (p 267) have been employed to control the atrial tachycardia resulting from digitalis intoxication [65] If these are ineffective procaine amide is administered (p 340)

Magnesium sulfate, 15 to 25 cc of a 20 per cent solution injected intravenously, 5 cc at a time, has been effective in the control of paroxysmal tachycardia [226 64 100]

Other recommended measures with which I have had few experiences or little or no success include the oral administration of syrup of ipecac, 8 to 16 cc (2 to 4 drams), repeated if necessary until vagal stimulation is sufficient to induce vomiting, or the hypodermic administration of apomorphine (5 to 10 mg or 1/12 to 1/6 grain) Both of these procedures are drastic and rarely necessary In a few cases atabrine has controlled attacks of paroxysmal tachycardia [57] An intravenous injection of 0 4 gm of atabrine has restored sinus rhythm in a case of nodal tachycardia within 45 seconds [50]

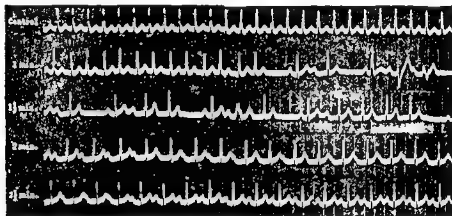

Fig 71 Paroxysmal atrial tachycardia Effect of 25 mg of Mecholyl Occasional slowing with sinus beats after one minute In lowest strip sinus rhythm with sinus tachycardia rate 130 per minute In next half minute normal rhythm with rate of 90

Quinidine is sometimes effective when all other measures have failed (For dosage, administration and toxicity, see p 368)

For prolonged attacks which do not respond to other measures, sedatives are usually necessary Bromides phenobarbital or chloral are most generally employed Occasionally morphine is justifiable and effective especially in the presence of distressing dyspnea shock or pain, but it is rarely needed and is contraindicated when attacks recur at relatively brief intervals The application of an ice bag to the precordium often affords psychologic and perhaps more specific benefit Reassurance is important

Treatment of Paroxysmal Tachycardia in Infants. This form of tachycardia is often associated with very rapid ventricular rate and heart failure and is notably (but not in

variably) resistant to carotid sinus massage and anti arrhythmic drugs But digitalization is usually effective Cedilanid is given intra muscularly or intravenously in an initial dose of 0 5 to 2 0 cc (0 1 to 0 4 mg or 0 01 mg per pound) Subsequent dosage is determined by the clinical response The simultaneous ad ministration of a sedative is desirable Oxygen therapy may also be valuable When there is no urgency digitalization may be effected by oral digoxin in a dose of 0 03 mg per pound in three divided doses in a period of 16 to 24 hours Digitalization is maintained for a week with one-tenth the digitalizing dose daily If the arrhythmia persists after full digitaliza tion, quinidine should be administered 100 mg orally every three hours for five doses or until the tachycardia stops Digitalization is main tained during quinidine therapy Phenyl ephrine 0 1 to 0 5 mg intravenously has been used successfully Morphine and anti biotics are important additional measures in the presence of congestive heart failure and pulmonary congestion or pneumonia

Prevention of Attacks The prevention of frequent attacks of paroxysmal tachycardia is difficult because of ignorance as to the under lying or precipitating cause All of the meas ures advised in the treatment of frequent extrasystoles should be employed (p 339) including the avoidance of emotional tension fatigue, tobacco coffee and alcohol indiges tion and constipation, unusual effort or exertion

Among drugs mild sedatives may be use ful but *quinidine* and *digitalis* are most de pendable The dosage of quinidine may start at 0 3 gm (5 grains) every two hours for six doses and may be increased gradually up to 4 gm (60 grains) daily in divided doses if necessary When the controlling dose is found it may have to be continued for months or years if the attacks recur when the drug is omitted Quinidine thus administered may eliminate recurrences entirely or diminish their frequency If quinidine is ineffective digitalization with continued maintenance doses of digitalis may prevent future attacks Digitalis is especially desirable in elderly pa tients with frequently recurring attacks

ATRIAL FLUTTER

This is a form of rapid heart action in which the atria beat regularly at a rate of 250 to 350 per minute The term flutter was first em ployed by MacWilliam[127] to describe the response of the atria to faradic stimulation Clinical features of atrial flutter were first described in detail by Jolly and Ritchie in 1910[99] Usually there is a 2 1 or some other fixed a v block, and the ventricles beat reg ularly at rates of 125 to 160 per minute Ventricular rates as high as 300 per minute may occur usually in infants in whom all the atrial impulses produce ventricular contrac tions An irregularity of the ventricular rate may result from changing a v conduction and altered degrees of a v block

Atrial flutter is encountered much less commonly than either atrial fibrillation or atrial tachycardia to both of which it is re lated in mechanism Conversion from atrial flutter to fibrillation occurs commonly, es pecially after the administration of digitalis Within the same electrocardiogram one may observe portions in which it is difficult to dis tinguish between atrial flutter and fibrillation or occasional shifts from atrial flutter to fibrillation and vice versa This is termed im pure flutter or flutter fibrillation

Atrial flutter usually occurs in paroxysms which persist much longer than those of atrial tachycardia, lasting many days weeks or months When flutter lasts more than two to three weeks, it is termed established flutter This type may persist indefinitely unless controlled by therapeutic measures Cases of *chronic atrial flutter* have been described[89, 108]

Mechanism

The mechanism of atrial flutter has usually been explained by either the theory of (a) "circus movement" or (b) repetitive stimuli from an ectopic focus in the atrium The theory of circus movement or circus rhythm was promulgated by Thomas Lewis[121] and his school and was widely invoked in the English speaking countries whereas the theory of repetitive stimuli from an ectopic focus was promulgated by Rothberger[146] and the Vien nese school Until recently, any controversy between these theories was usually confined to the quiet composure of the physiology classroom Since about 1949 the development of newer experimental techniques and numer ous experimental and clinical observations have revived the conflict between these theories without as yet a clear decision as to which applies to clinical atrial flutter

Circus Rhythms Circus rhythms or circus

movements were first induced in the umbrella of the jelly fish by Mayer,[135] who blocked a local area and applied a stimulus on one side of the block. The excitation wave thus initiated traversed the ring of the umbrella in a unidirectional fashion away from the block. If on completing the circuit and reaching the previous site of the block near its origin, the impulse (or wave) found the block gone and the tissue therefore no longer refractory, it continued to circle the ring a second, third, fourth time, etc. If no block had been set up at the original moment of stimulation, an excitation wave was able to spread along the ring in both directions (clockwise and counterclockwise) from its origin until both forward portions met and neutralized each other halfway along the circumference.

Further researches by Mines,[illegible] by Garrey[146] and by Lewis and his associates[131] disclosed that circus rhythms depended on (1) extreme shortening of the refractory period of the heart muscle, (2) slowing of the rate of conduction of an excitation wave, (3) local areas of block (or depressed excitability) and (4) rings of sufficiently large circumference.

Support for the theory of circus movement was recently found in the experimental studies of Rosenblueth and Garcia Ramos[165] (infra) and in curves of the momentary atrial electrical axes.[45] In cases of atrial flutter and fibrillation the curves of these axes were roughly circular, while the curve in cases of paroxysmal tachycardia resembled that of sinus rhythm.

According to Lewis et al., atrial flutter is due to an ectopic atrial impulse which traverses a circular path around the orifices of the superior and inferior venae cavae at an absolutely regular rate of about 250 to 350 per minute.[131] On returning to the ectopic center the impulse finds its site of origin no longer refractory. The original impulse thus reenters the circuit and continues around the same ring of muscle. According to this theory, the atrial rate is determined by the speed with which the impulse traverses the circuit and this, *in turn, by the conductivity, refractory* period and length of the circus ring of muscle. From the "circus" excitation wave, sometimes called the central or mother wave, centrifugal waves are said to flow uniformly and regularly to the various parts of the atrial musculature. This results in weak but distinct atrial contractions.

Theory of Repetitive Stimuli from an Ectopic Focus. Rothberger[166] and his school adhered to the theory that stimuli arising in ectopic or "parasystolic" foci were responsible for premature (ectopic) beats and also that repetitive stimuli from such foci produced paroxysmal atrial tachycardia, atrial flutter or atrial fibrillation, depending on the rate of impulse formation.

This concept was supported by recent studies of Scherf,[177] who devised a method for producing atrial arrhythmias including atrial flutter for prolonged periods, by the application of aconitine to a local area of the dog's atrium. Previously such atrial arrhythmias could be induced for only very brief periods during or shortly after electrical stimulation of a local atrial site. Scherf and associates found that cooling the aconitine site after the production of atrial flutter caused the flutter to disappear; the flutter reappeared when cooling was discontinued. These findings appeared incompatible with the concept of self-perpetuating circus movement. They concluded that atrial flutter was due to a continuous discharge from an ectopic focus, whereas atrial tachycardia results from rapid, interrupted discharges from such a focus.[176,177]

Prinzmetal and associates[157,118] in a series of beautifully conceived and executed studies, utilizing the aconitine technique for inducing atrial arrhythmias, found considerable evidence that both atrial flutter and fibrillation occur when an ectopic atrial focus discharges impulses at rapid rates. Observations by high speed cinematography indicated that the flutter wave travelled away from the aconitine focus in all directions and did not return toward the focus or form a circulating wave. Furthermore, direct leads were recorded from various sites throughout the interatrial septum and both atria, including the body of the left atrium which had not been previously explored in this manner. By timing the intrinsic deflections and studying the configuration of the recorded electrocardiograms, they concluded that the flutter wave started at the *ectopic focus and radiated simultaneously in* all possible directions.

Spontaneous atrial flutter in man was also studied by high speed cinematography of the atria observed at a cardiac operation[158] and by simultaneous multiple esophageal, precordial and limb lead electrocardiography. The films showed simultaneous contraction of the right

and left atrial appendices whereas one or the other would have preceded if appendiceal contraction resulted from a stimulus pursuing a circus movement The simultaneous esophageal electrocardiograms taken from different atrial levels indicated that the impulse responsible for atrial flutter usually arises in and travels away from the caudal region of the atrium (negative electrocardiographic deflection) whereas in the cephalic region of the atrium there was a positive deflection denoting passage of the impulse toward the cephalic region In the midatrial region there was a positive-negative diphasic complex indicating passage of the impulse toward the electrode at that site followed by passage away from the site toward the cephalic region If the circus theory applied one would expect identical deflections in esophageal leads from all atrial sites

On the other hand studies of esophageal and precordial leads in patients with atrial flutter by Cabrera Cosio and Sodi Pallares[97] and of endocardial and esophageal electrocardiograms and vectorcardiograms in such patients by Grishman et al [8] and of endocardial and esophageal electrocardiograms by Wenger and Hofmann Credner[207] were all interpreted as supporting the concept of circus movement The problem in evaluating these conflicting reports based on esophageal and precordial electrocardiograms is due at least in part to inability to follow the entire path pursued by the atrial excitation wave and the frequent difficulty in timing the intrinsic deflections accurately

It is highly probable at least in the experimental animal that the mechanism of atrial flutter is not a unitary one and that both repetitive stimuli from a single or multiple foci and circus rhythms may be responsible under different circumstances Aconitine induced atrial flutter may be due to the first mechanism On the other hand Rosenblueth and Garcia Ramos[183] established prolonged flutter by first crushing the intercaval bridge thus producing an area of block between the mouths of the venae cavae and then applying electrical stimulation to the right atrium The atrial flutter thus produced is generally accepted as being the consequence of a stimulus traveling in a circus movement The response of atrial flutter to various agents differs according to its production by aconitine or rapid electrical stimulation[33 131] additional evidence that experimental atrial flutter may be due to different mechanisms

In conclusion there is as yet no general agreement as to whether atrial flutter which may have a varied mechanism in the experimental animal is due to a circus movement or rapid stimuli from an ectopic focus in man Various modifications of both theories have been suggested to explain the controversial data[200]

Relation of Atrial Flutter to Paroxysmal Tachycardia and Other Atrial Arrhythmias A close relationship between the various atrial arrhythmias has long been indicated by the clinical observation of a gradual or rapid transition from isolated ectopic beats to paroxysmal (atrial) tachycardia atrial flutter and atrial fibrillation in the same patient The administration of drugs such as quinidine may result in rapid transitions from one to the other atrial arrhythmia As a rule atrial premature beats and atrial tachycardia appear in the same patient as do atrial flutter and fibrillation but rarely atrial tachycardia and atrial flutter In the experimental animal all four of the above-mentioned atrial arrhythmias could be produced depending on the rate of electrical stimulation Accordingly it has been suggested that these atrial arrhythmias have an identical origin e g rapid stimuli from an ectopic focus but that the specific resulting arrhythmia depends on the rate of stimuli formation Extrasystoles appear if the rate of discharge from the ectopic focus is less than that from the sinus node and tachycardia flutter fibrillation at progressively faster rates from about 180 to 600 per minute

Nevertheless in their clinical behavior paroxysmal atrial tachycardia and atrial flutter differ sufficiently to indicate that these arrhythmias may be caused by different mechanisms Atrial tachycardia usually occurs in normal hearts flutter in diseased hearts Atrial tachycardia responds readily as a rule to carotid sinus pressure (vagal effect) Mecholyl and sympathomimetic amines with restoration of sinus rhythm whereas atrial flutter does not so respond Digitalis often converts atrial flutter to fibrillation whereas atrial tachycardia is restored to sinus rhythm without the intermediary of atrial fibrillation

Atrial tachycardia and flutter are not absolutely distinguished by the atrial rate since

occasionally atrial tachycardia is associated with atrial rates of about 300 per minute, whereas in atrial flutter the atrial rate is occasionally less than 225 per minute It has been suggested that the important difference is not the atrial rate as such but the inability of the atrioventricular bundle to conduct all of the e atrial stimuli in atrial flutter Hence atrioventricular block is common in atrial flutter, very rare in clinical atrial tachycardia, except that due to digitalis intoxication or electrolyte disturbances[131 70] The classic electrocardiographic distinction between paroxysmal atrial tachycardia and atrial flutter is the presence of continuous oscillations without isoelectric intervals in atrial flutter (Fig 75) There is often a sharp upstroke with a more gradual downstroke forming a characteristic series of continuous oscillations resembling saw teeth (F waves) without distinct isoelectric intervals However, Prinzmetal and associates[1 7] discovered isoelectric intervals corresponding to atrial diastole in 95 per cent of 139 cases of spontaneous atrial flutter The undulatory pattern of the flutter waves was said to be composed of two components a P wave of depolarization followed by a Ta wave of repolarization The P waves are best seen in leads II and III of the standard leads and are indistinct in lead I because the presumed pathway of the ectopic impulse is perpendicular to the direc

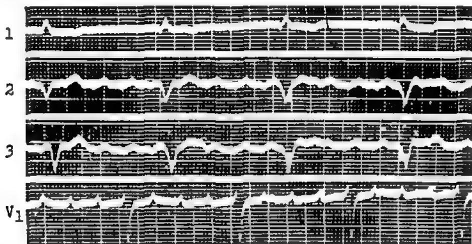

Fig 72 Atrial flutter in a man aged 61 year with anteroseptal and diaphragmatic infarction 4 1 ventricular response observed in lead V_1 Ventricular rate 50 atrial rate 200 per minute

tion of lead I whereas its course is more nearly parallel to the direction of leads II and III In most cases of flutter, the P wave is inverted in leads II and III suggesting that the excitation wave arises in the caudal portion of the atrium less frequently there is an upright P wave in leads I and II indicating that the ectopic focus is in the cephalic portion of the atrium Most of the precordial leads do not usually disclose the P waves distinctly, however the P waves are usually well displayed in leads from the right side of the sternum (V_1 V_{3R}), e g, by placing the exploring precordial electrode in the third right interspace[5] The latter or esophageal leads should always be obtained in the study of any paroxysmal tachycardia especially in cases in which a rapid ventricular rate obscures the P waves They are particularly helpful in dis-

But this has been challenged by Prinzmetal et al[157 158]

Conduction of all the very rapid atrial impulses to the ventricle is rarely possible Occasionally in infants and rarely in adults[157] there is a 1 1 ventricular atrial rate the ventricles contracting regularly 250 to 300 times a minute But as a rule there are varying degrees of partial heart block (2 1, 3 2 3 1, etc) Most commonly the ventricular rates vary between 100 and 150 per minute and there is a 2 1 block With higher degrees of block, e g, 4 1, the ventricles may beat regularly and at normal rates (Figs 72 75) Complete heart block with atrial flutter has also been noted[11 115]

The Electrocardiogram

The *P waves* are absolutely regular in rhythm at rates of 250 to 350 per minute

closing atrial flutter with 2 1 block Often the typical flutter waves are seen distinctly in aV$_F$

The *P R interval* is prolonged but it is often difficult to measure It may vary from beat to beat especially in cases with varying grades of a v block [79] Even with unaltered grades of heart block e g 2 1 slight alterations in the R R interval may result from corresponding changes in the P R interval

The *QRS complexes* usually recur regularly at rates of 75 to 150 per minute except as noted above with changing P R intervals or degree of a v block Rarely there is a 1 1 block with ventricular rates of 250 to 300 or more In cases of atrial flutter with 1 1 response or even with 2 1 response the P waves may be obscured and the sequence of QRS complexes resembles a ventricular tachycardia (Fig 73) Atrial flutter with bundle branch block may also simulate ventricular tachycardia (Fig 74) Most commonly a QRS complex follows every second P wave occasionally every third or fourth P wave In such instances every second third or fourth P wave may be fused with or obscured by the QRS complex In long electrocardiographic strips there may be seen changing grades of block but usually there is a dominant degree of heart block Similarly the P R interval may vary in length but there is a tendency to return to a dominant time interval [79] The Wenckebach phenomenon may occur in association with atrial flutter and varying block [28] Atrial flutter may be associated also with complete heart block and usually presents itself as chronic atrial flutter [23]

If an electrocardiogram is taken during carotid sinus pressure the atria are found to be unaffected while the ventricular rate is slowed and the degree of a v block may be increased Occasionally momentary cardiac standstill may occur These effects result from vagal stimulation which impairs conduction through the a v node Digitalis usually produces similar effects The intravenous administration of procaine amide may aid in differentiating atrial flutter with bundle branch block from paroxysmal ventricular tachycardia [III] In ventricular tachycardia the QRS complexes remain regular or become regular and their conformation changes

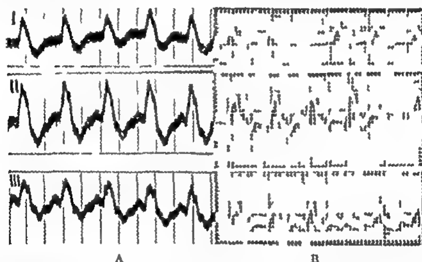

Fig 73 A Atrial flutter with 2 1 response resembling ventricular tachycardia Presence of flutter confirmed by jugular venous tracing
B Same case After digitalization flutter waves clearly seen especially in lead III

Etiology

Atrial flutter, like fibrillation and unlike atrial tachycardia is observed more commonly with heart disease than in its absence Its greatest frequency is with rheumatic heart disease and mitral stenosis but it may also be associated with hyperthyroidism (p 1006) or with coronary and hypertensive heart disease [102] It occurred in 20 of 1247 cases of myocardial infarction [19] The tachycardias of infancy occurring usually in the first month of life are generally unaccompanied by an

underlying cardiac affection but may be due occasionally to rhabdomyoma of the conduction system or other myocardial disease Cases of *congenital* paroxysmal tachycardia[3] have been distinguished from those commencing in the early months of infancy by their equal occurrence in males and females and by the predominance of atrial flutter in the congenital cases Atrial flutter may be observed with mediastinal disease and during surgical procedures especially those in the thoracic cavity[83] Occasionally it appears in patients without apparent heart disease either spontaneously or because of alleged nervous or physical strain or respiratory infection Atrial flutter occurs commonly during the administration of quinidine to patients with atrial fibrillation[199] it is rare manifestation of digitalis toxicity[44]

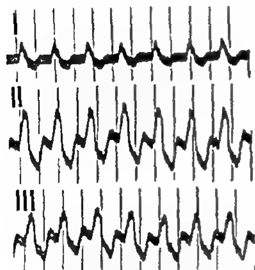

Fig 74 Atrial flutter with bundle branch block simulating ventricular tachycardia.

Symptoms and Signs

The symptoms are those of any sudden paroxysmal tachycardia namely palpitation anxiety ranging to alarm of impending death weakness dizziness or syncope and possible symptoms and signs of congestive heart failure or shock, as detailed under paroxysmal atrial tachycardia (p 346)

The paroxysmal tachycardia of early infancy may be due to atrial flutter While the tachycardia may be discovered accidentally it is usually documented by the infant's refusal to take food, vomiting, restlessness pallor, and later cyanosis striking rapid enlargement of the liver, dyspnea with noisy respiration, pulmonary edema and other evidences of congestive heart failure[137] [illegible] (p 347)

The heart rate in atrial flutter is rapid and usually regular despite rest, exercise or change of posture Auscultation of the heart discloses apical rates of 125 to 160 when there is 2 1 block but the rate may be 75 or 100 with blocks of 4 1 or 3 1 respectively Sometimes there is a sudden change in rate from 160 to 80 as the degree of block alters from 2 1 to 4 1 Carotid sinus stimulation usually increases the degree of block When the ventricular response and therefore the cardiac beats are irregular exercise may raise the ventricular rate and induce a constant degree of block and a regular heart beat A changing intensity in the first heart sound in cases with irregular ventricular response may be due to the alterations in the P R interval [illegible] The atrial contractions in atrial flutter with high grade heart block may be heard as distinct clicks[149] [illegible]

Inspection of the cervical veins may disclose distinct "a" waves of atrial contraction which are two three four or more times as frequent as the apical (ventricular) waves When present these "flutter" waves are diagnostic

There may also be physical signs of an underlying cardiac disease or of associated circulatory failure The circulatory dynamics are determined essentially by any intrinsic cardiac disease Conversion of the flutter to sinus rhythm may[4] or may not[137] induce an increase in the resting cardiac output

Prognosis

The attack of flutter is apt to be more disturbing than that of atrial tachycardia because of its greater tendency to persist (days weeks months or years)[44] Cases of atrial flutter lasting eleven years[10] twenty four years[133] and twenty six years[10] have been reported Sometimes it is very difficult to alter the atrial flutter or to reduce to ventricular rate satisfactorily despite full doses of digitalis or quinidine Because of the prolonged duration and the frequency of underlying heart disease atrial flutter is apt to be complicated by the development of congestive heart failure However it is remarkable how patients with normal heart despite atrial flutter, or with ventricular tachycardia of months or years' duration suffer no visible deterioration of their cardiac function Sometimes the

attacks are disabling by their very persistence even when circulatory function remains adequate Embolization occurs occasionally Relapses of flutter occur frequently after sinus rhythm has been restored Often atrial flutter is followed sooner or later by atrial fibrillation This may occur spontaneously or in response to digitalis therapy

Treatment

Treatment consists essentially in the administration of digitalis or quinidine *Digitalis* is usually given first trial and is employed to slow the ventricular rate and to control or prevent heart failure The digitalis should be given in full doses i e until the desired therapeutic effect is obtained Often speedy digitalization is desirable and is effected by the intravenous administration of lanatoside C (8 cc or 1 6 mg) (p 263) Distinct signs of toxicity may appear with effective dosage (For doses and methods of digitalization see p 259) The ventricular rate is usually reduced to the normal range by an increase in the degree of av block or the flutter may be converted to atrial fibrillation and the ventricular rate is slowed to desired levels (Fig 75) In either circumstance daily maintenance doses of digitalis (p 261) may be continued as required to maintain the desired apical rate Digitalization may be followed by prompt restoration of sinus rhythm without the intermediation of atrial fibrillation Sometimes in cases with induced atrial fibrillation discontinuation of the digitalis is followed by a reversion from atrial fibrillation to normal sinus rhythm If not the necessary doses of digitalis should be resumed or an effort be made to restore normal sinus rhythm with quinidine

Quinidine may be administered as described below under atrial fibrillation whenever atrial flutter or atrial fibrillation persists after digitalis therapy When atrial flutter is treated with quinidine there may be a progressive reduction in the degree of block from 4 1 to 2 1 and 1 1 the latter being associated with an extremely rapid ventricular rate and sometimes with disabling and alarming clinical manifestations [133] As a rule this is transient and the previous block is restored with discontinuation of quinidine Carotid sinus massage may terminate an attack of atrial flutter with 1 1 conduction In cases of frequent relapsing atrial flutter quinidine may also be given after an attack is controlled in the hope of preventing or minimizing recurrences

Although *procaine amide* (Pronestyl) is usually most effective in ventricular arrhythmias it may also be effective in atrial arrhythmias Restoration of sinus rhythm has been reported in atrial flutter with 1 1 block following 6 cc (0 6 gm) of Pronestyl intravenously [55] However as a rule Pronestyl is ineffective in terminating atrial flutter [2] although the atrial rate may be slowed [184]

Reassurance avoidance of emotional and physical stresses when possible and elimination of tobacco coffee and alcohol indigestion constipation and other factors which may seem to contribute to the attacks should all be considered as accessory therapeutic measures

Fig 75 Atrial flutter Effect of digitalis Feb 25 atrial flutter with 2 1 response Atrial rate 340 Ventricular rate 170 Feb 27 4 1 response Ventricular rate 85 Patient digitalized Four days later atrial fibrillation Digitalis discontinued Mar 4 return of regular sinus rhythm

ATRIAL FIBRILLATION

This is an arrhythmia characterized by extremely rapid irregular atrial impulses by ineffectual vermicular atrial contractions and by irregular rapid ventricular beats Cushny and Edmunds[49] first interpreted atrial fibrillation in man as synonymous with the perpetually irregular pulse of Hering[101] and the physiologist s delirium cordis Rothberger and Winterberg[167] and independently Lewis[126] proved this electrocardiographically

Atrial fibrillation is one of the two or three commonest and probably the most important of all the disorders of the heart beat It may occur as paroxysms of an irregular tachycardia or more often it becomes established as a permanent condition

Mechanism (See also p 1003)

The mechanism of atrial fibrillation like that of atrial flutter has been explained by

either the theory of circus movement or the theory of rapid discharges from one or more ectopic foci. This has been discussed in some detail above (p. 352). That atrial flutter and fibrillation are closely related is indicated by their frequent association in laboratory animals and humans and their frequent change from one to the other, especially as a result of drugs. Consequently, their mechanism is regarded as similar. Lewis[131] concluded that both were due to a circus rhythm but that the actual rhythm was regular in flutter, irregular in atrial fibrillation. Recent support for the circus movement theory for atrial fibrillation as for atrial flutter (p. 352) was contributed by the observations of Rosenblueth and Garcia Ramos,[165] who produced atrial fibrillation by electrical stimulation after blocking or crushing the intercaval bridge of tissue.

Rothberger[166] believed that atrial fibrillation arose as a result of rapid discharges from an ectopic focus. Scherf concluded that atrial fibrillation produced with aconitine was due to a continuous discharge from a single ectopic focus, whereas that produced with acetylcholine was of multifocal origin.[177]

Prinzmetal et al. made direct observations on the fibrillating atria of patients undergoing cardiac surgery with the aid of high speed cinematographs and direct atrial leads.[159] Heterorhythmic large (L) contraction waves at an irregular rate of 250 to 400 per minute were noted and corresponding irregular atrial electrocardiographic complexes at the same rate, presumed to correspond to the f waves seen in the standard leads of the electrocardiogram during atrial fibrillation. The configuration of these irregular varying complexes and their occurrence at different rates in the two atria were regarded as findings which were incompatible with the circus movement theory and supporting that of rapid stimuli from ectopic foci. Similar studies of atrial fibrillation produced experimentally in animals by aconitine or electrical stimulation disclosed chaotic, bizarre and heterorhythmic atrial motion. Large grossly visible L contractions were observed at the rate of 400 to 600 per minute and minute asynchronous contractions and dilatations (*M activity*), *best seen under high magnification*. Corresponding electrical activity was recorded. These observations were also interpreted as incompatible with the circus movement theory. Prinzmetal et al.[159] have stressed the failure of the atrial myocardium to conduct these extremely rapid impulses as a prerequisite to the development of atrial fibrillation. Atrial fibrillation either follows atrial flutter or is initiated by an extrasystole occurring during the vulnerable period of the cardiac cycle. Myocardial disease or dysfunction and aging predispose. It is presumed that the atria are unable to respond in a coordinated manner both because of the excessively *rapid impulses arising from an* ectopic focus and because of a deficiency in the atrial musculature.

Atrial Behavior in Atrial Fibrillation. There is no definite coordinated universal atrial contraction or diastolic relaxation. Instead there are irregular, dissociated contractions at *about 400 per minute*, which produce wormlike (fibrillary) quiverings of the atria without an effective atrial contraction. So-called impure flutter or flutter-fibrillation represents an intermediary or transition phase between flutter and fibrillation, combining features of both disturbances.

Ventricular Behavior. Like atrial flutter, atrial fibrillation is associated with various degrees of a-v block. But because of the more rapid atrial rates in fibrillation, fewer impulses can reach or excite the ventricles and, because the atrial rhythm is irregular, the ventricular rhythm in atrial fibrillation is also irregular. Only about one out of three or one out of four atrial impulses gains access to the ventricles, and consequently the ventricular rate usually varies between 100 and 140 per minute. In patients without organic heart disease and in the paroxysmal type of atrial fibrillation, higher rates even approaching 180 to 200 may be observed.

Under certain circumstances atrial fibrillation is associated with ventricular contractions which are *irregular in rhythm* but *normal or slow in rate*.

1. In *partial heart block* due to underlying rheumatic myocarditis, calcific aortic stenosis or severe coronary artery disease, the ventricular rate may range between 90 and 40 per minute.

2. *Carotid sinus pressure*, by causing reflex vagal stimulation, depresses a-v conduction and slows the ventricular rate.

3. *Digitalis*, by direct action on the a-v node and bundle, diminishes atrioventricular conduction and in therapeutic doses may slow the ventricular rate to between 60 and 80 per

minute Thus, when patients with atrial fibrillation are adequately digitalized their heart beat if sufficiently slowed may appear to be regular The irregularity becomes clear if the rate is increased by exercise or amyl nitrite

Under other circumstances the *ventricular contractions* in cases of atrial fibrillation may actually become *regular* with slow or rapid rates as follows

1 *Complete heart block* in association with atrial fibrillation No atrial impulses are transmitted to the ventricles and the latter respond regularly and slowly to their own pacemaker (idioventricular rhythm) Exercise does not restore the irregularity

2 *Ventricular paroxysmal tachycardia* The ventricles respond rapidly and regularly to stimuli from an ectopic ventricular center and prevent excitation by stimuli from the fibrillating atria

capacity for physical exertion Furthermore the baneful effect of atrial fibrillation is indicated by the occurrence of heart failure in subjects with atrial fibrillation without apparent underlying heart disease In a series of 84 patients with atrial fibrillation who had no apparent organic heart disease there was evidence of frank or latent heart failure in fourteen [154] After conversion of the atrial fibrillation to sinus rhythm the increased cardiac size abnormal dynamics and heart failure were restored to normal

The Electrocardiogram

The characteristic electrocardiographic features of atrial fibrillation are (Fig 76)

1 *Absence of P waves* But there are usually continuous slight undulations known as f or fibrillation waves Sometimes these are visible only in precordial leads taken from the right side of the sternum or in esophageal leads [84]

Fig 76 Atrial fibrillation 8/21/40 regular sinus rhythm 8/7/43 atrial fibrillation Irregular rapid ventricular rate about 120 to 160 P waves absent 8/11/43 patient digitalized Atrial fibrillation persists but ventricular rate is slowed to about 75 per minute Coarse atrial fibrillary undulations but no distinct P waves

Effect on Cardiac Function The absence of effective atrial contraction removes a significant factor in the filling of the ventricles According to the observations of Lewis[1 8] and of Wiggers and Katz [13] this may amount to 20 to 30 per cent of the total ventricular contents Studies of cardiac output suggest that it is considerably reduced during atrial fibrillation for with the restoration of sinus rhythm the cardiac output increases 25 to 30 per cent [117 119 81] Increased cardiac output during exercise after conversion to sinus rhythm was reported by Kory and Meneely [118] Hecht et al [46] and others [33] The ability to increase cardiac output may be lost despite conversion to sinus rhythm if there is an underlying tight mitral stenosis or severe congestive heart failure From the clinical viewpoint it appears that fibrillation of the atria does not significantly impair cardiac function if the ventricular rate is sufficiently slowed to permit adequate diastolic filling However the advantage of sinus rhythm over atrial fibrillation may become apparent in an increased

2 *Irregularly spaced QRS complexes* They also vary somewhat in their configuration Occasionally notching slurring or widening of the QRS complex (intraventricular conduction disturbance) due to fatigue of the conduction tissues is observed in cases with ventricular rates of 180 or more

In cases of impure flutter there are occasional series of regular or almost regular P waves which vary in contour (sometimes termed F waves or P) However the R R intervals change from cycle to cycle In other portions of the same record the P waves disappear altogether and are replaced by f waves Flutter fibrillation is a term sometimes applied to these impure flutters which vary from moment to moment in their resemblance to flutter or fibrillation respectively (Fig 77)

Etiology

Atrial fibrillation occurs most commonly in cases of mitral stenosis (rheumatic heart disease) coronary heart disease with heart failure and hyperthyroidism [45 110] When es

tablished atrial fibrillation complicates hyperthyroidism there is often a simultaneous mitral stenosis or severe coronary disease (p 999) Paroxysmal atrial fibrillation is particularly identified with hyperthyroidism although it is also associated with a variety of other conditions Masked hyperthyroidism *may be overlooked as the cause of atrial* fibrillation Bortin and associates [illegible] utilizing radioactive iodine uptake for diagnosis discovered 8 instances of previously undetected hyperthyroidism among 35 cases of atrial fibrillation of uncertain etiology but attributed to coronary or rheumatic heart disease on insufficient grounds Atrial fibrillation *may occur in any type of heart disease es-*dition In particular, I have observed atrial fibrillation after surgical operation in the thorax[2] and also in the abdominal cavity, during pneumonia and less often with other infections with pulmonary and mediastinal carcinoma and mediastinal lymphomata after burns with biliary and renal colic and with visceral embolization and infarction, especially pulmonary embolization In some of these conditions I have strongly suspected the presence of underlying cardiac disease as a predisposing factor In others there is direct invasion of the heart muscle by neoplasm or inflammatory tissue

There are however also instances of purely *functional chronic atrial fibrillation without*

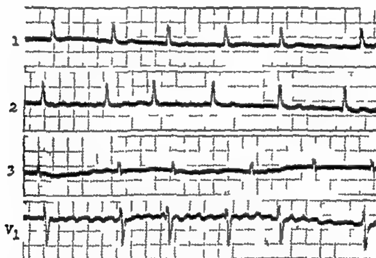

Fig 77 Atrial fibrillation with flutter fibrillation V_1 shows prominent fibrillation (f) waves resembling flutter (F) waves Ventricular rate 70 80 per minute and rhythm completely irregular Atrial rate in V_1 approximately 300 per minute and irregular

pecially in association with congestive heart failure It is also not infrequent in the first two weeks after an acute myocardial infarction when it appears as a paroxysmal occurrence which usually subsides spontaneously after several hours Askey[10] reported 84 instances of atrial fibrillation among 1247 cases of acute myocardial infarction Atrial fibrillation has been reported in cases of hemochromatosis in which hemosiderin pigment was demonstrated at autopsy in the atrial and ventricular myocardium [11,14]

Although atrial fibrillation is usually associated with severe organic heart disease it is occasionally discovered in patients with apparently normal hearts in whom the arrhythmia is precipitated by some noncardiac conanatomic disease of the heart occurring in 5 or 6 per cent of all cases of atrial fibrillation [1,6,47] In some tobacco alcohol or other toxic factors appear to be precipitating or contributory causes There are reports of cases of atrial fibrillation in acute nicotine poisoning[2] and following the prolonged use of thyroid extract [99] In others fatigue emotional stress or violent exertions have been indicted but there may be no apparent cause whatever Rarely atrial fibrillation may be induced by carotid sinus pressure [149] Familial occurrence has been reported[1,6,13], I have observed two brothers with atrial fibrillation without apparent organic heart disease who were said to have had this condition paroxysmally since youth and for at least twenty

years Since this was first written I have seen the 28 year old son of one of these brothers for recurrent paroxysmal atrial fibrillation without apparent heart disease

Paroxysmal atrial fibrillation may occur with any of the above conditions but it is especially associated with hyperthyroidism (p 1006) The atrial fibrillation observed after thoracic surgical procedures pneumonia etc lung disease, females predominate in hyperthyroidism and mitral stenosis males in coronary heart disease

Symptoms

Symptoms referable to atrial fibrillation vary considerably and are often obscured by the symptoms of the associated cardiac or noncardiac disease In paroxysms of atrial fibrillation or at the onset of permanent fibrillation the ventricular rate is usually very rapid and the symptoms are those already described under paroxysmal tachycardia (p 346) Most commonly there is palpitation but there may also be precordial oppression or pain anxiety or agitation and weakness or dizziness *The first or subsequent paroxysms may announce themselves by an* attack of syncope due to complete cardiac standstill of several seconds duration when

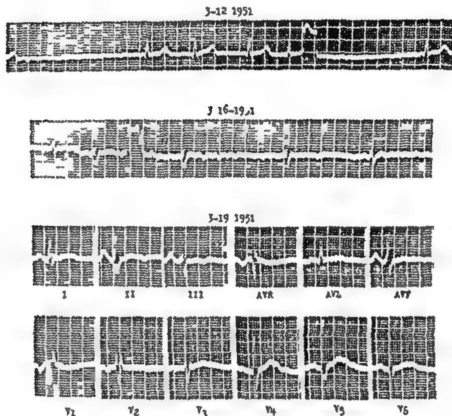

Fig 78 Man 35 years old with 10 year history of atrial fibrillation without evidence of organic disease Electrocardiogram during attack of syncope

3-12 51 Period of ventricular asystole in recumbency Extreme hypotension on arising

3-16-51 Atrial fibrillation with shorter periods of ventricular asystole after 0 8 mg atropine intravenously

3 19-51 Sinus rhythm established after 3 2 gm quinidine in 24 hours Prominent wide P waves in leads 2 3 aVR and aVF RR pattern in V to V and prominent U waves Intraatrial and intraventricular conduction defects and U waves due to quinidine

is usually paroxysmal in character and of brief duration

Atrial fibrillation occurs at any time between childhood and old age but most frequently after forty [140] As might be anticipated, the average age of patients with atrial fibrillation and coronary heart disease is about twenty years more than that of patients with rheumatic heart disease and this arrhythmia The ex incidence in cases of atrial

atrial fibrillation Symptoms of congestive failure or shock are apt to appear only if the tachycardia is very rapid (over 180) or if the attack is prolonged and the underlying cardiac disease has already greatly impaired myocardial reserve However congestive heart failure has been observed to result from uncontrolled atrial fibrillation in an otherwise normal heart [154] Syncope as well as dizziness occurs occasionally in chronic atrial fibrillation[154] as well as at the onset of a paroxysm [45] In one patient with atrial fibrillation for 10 years, with an apparently normal heart, the attacks of syncope ceased after sinus rhythm was restored by quinidine[73] (Fig 78)

Established atrial fibrillation is usually better tolerated than the paroxysmal type, partly because the rate is slower and partly because the patient becomes adjusted to the disturbance For these reasons the symptoms in established atrial fibrillation are usually those of heart failure and not of the arrhythmia Occasionally atrial fibrillation is discovered in patients who are completely unaware of any cardiac disorder In some atrial fibrillation is present on certain days and sinus rhythm at other times Nevertheless there may be no detectable difference in the patient's sense of well being Asymptomatic atrial fibrillation with slow ventricular rate may become distressing if the ventricular rate becomes accelerated by exercise emotional excitement febrile disease or drugs It is apparently the tachycardia rather than the ventricular irregularity that is chiefly and usually responsible for symptoms

Certain *complications* may be precipitated by a paroxysm or at the onset of permanent auricular fibrillation

1 *Heart failure* may be induced by the added burden of the irregular tachycardia on an already diseased heart The heart failure induced in some instances of atrial tachycardia is usually rapidly reversible with spontaneous or induced restoration of sinus rhythm But although the heart failure associated with atrial fibrillation may be controlled, it is usually chronic and requires continuous treatment thereafter

2 *Atrial thrombosis* is favored by the occurrence of atrial fibrillation For this reason atrial fibrillation is not infrequently a predisposing factor to cerebral, peripheral or visceral embolization and infarction Sometimes the emboli are dislodged when the atrial fibrillation reverts to normal rhythm spontaneously or after quinidine therapy Very occasionally in cases of mitral stenosis, the atrial thrombus formed after the onset of atrial fibrillation may continuously or intermittently obstruct the narrow mitral orifice (ball valve thrombus) causing a shock like picture and death (p 657) Of course atrial thrombosis may occur in mitral stenosis even with sinus rhythm if there is left atrial dilatation But it is probable that the absence of effective atrial contraction in atrial fibrillation is a major causative factor in thrombus formation Because of the danger of cerebral embolism, patients with atrial fibrillation are subject to sudden death According to Daley et al [illegible] 2 5 to 4 0 per cent of patients with atrial fibrillation die suddenly and unexpectedly

Signs

The distinctive physical sign is a complete irregularity of the heart beat This is most readily ascertained at heart rates of 100 to 140 Regularity may be simulated when the ventricular rate is under 90 or over 150 The pulse also is completely irregular At rapid ventricular rates however the pulse rate is usually considerably less than the apical rate, this difference is termed a pulse deficit It results chiefly from failure of the weak ventricular beats to open the semilunar valves and expel the column of blood which produces the radial pulse In part also the pulse deficit results from difficulty in counting weak pulse beats which are closely spaced Because of the possibility of a pulse deficit, it is essential that the heart rate be determined by cardiac auscultation, especially when this is being used as a guide to treatment

When treatment with digitalis has been instituted, the apical heart rate becomes slowed the beats become stronger and more uniform in amplitude, and the pulse deficit diminishes and then disappears If the patient is first seen at this stage of digitalization, the heart and pulse rate may be found within a normal range of 70 to 80 and the heart and pulse may appear to be regular or almost so

Heart Sounds The second sound may be absent when the ventricular contractions, which occur after a brief diastole and incomplete filling are too weak to open the semilunar valves The first sound varies in

loudness except when atrial fibrillation is associated with mitral stenosis [161]

Other physical signs are determined by associated cardiac or noncardiac disease Since mitral stenosis is the commonest underlying condition enlargement of the left atrium straightening or prominence of the left middle border of the heart and an apical diastolic murmur may be found The typical presystolic rumble is usually absent or difficult to elicit in the presence of atrial fibrillation If the heart rate is rapid the diastolic murmur is sufficiently close to the first sound to simulate a presystolic murmur When the heart rate is slow or the diastolic period is relatively long there is an early diastolic murmur

Diagnosis

For diagnosis and differential diagnosis of the tachycardias see page 378

Course and Prognosis

Paroxysms of atrial fibrillation usually last for several hours or occasionally for a few days When they persist for more than two weeks they usually are permanent unless specific treatment restores sinus rhythm Paroxysms may occur infrequently or several times a week Often a stage of paroxysmal atrial fibrillation precedes permanency of the arrhythmia The persistence and recurrence of paroxysmal atrial fibrillation are usually determined by some underlying cause such as hyperthyroidism or mediastinal disease The outlook then depends on the ability to discover and remedy the causative condition Atrial fibrillation developing from several days to two weeks after the onset of an acute myocardial infarction is almost always paroxysmal and of brief duration According to Brill [27] 90 per cent of paroxysms of atrial fibrillation subside within a week but occasionally one may continue for as long as a year and yet cease spontaneously On the other hand it is generally stated that once established atrial fibrillation tends to persist permanently Exceptions to this statement were reported by Burch [32] who observed atrial fibrillation of twenty two months duration replaced by sinus rhythm and by Fogel [73] who observed spontaneous return to normal sinus rhythm after a purported duration of eleven years

When paroxysmal atrial fibrillation occurs in a normal heart it may be quite disturbing because of symptoms due to the tachycardia because of the associated anxiety and rarely because of syncope or embolism But it is usually of no importance as regards the outlook for life or the development of heart disease [214] When paroxysmal atrial fibrillation occurs in a diseased heart the condition may be more serious because of the greater likelihood of precipitating congestive heart failure and the dangers of cerebral and peripheral ischemia embolism or sudden death

As a rule the development of persistent atrial fibrillation is an unfavorable prognostic sign In most instances it is associated with serious organic heart disease and its occurrence usually denotes advanced disease with congestive heart failure in the offing if not already present Persistent atrial fibrillation in patients with acute myocardial infarction is associated with a significantly higher mortality rate than in patients without this arrhythmia This may be a consequence of more extensive cardiac damage in the cases in which atrial fibrillation developed rather than of the arrhythmia itself Persistent atrial fibrillation in patients with hyperthyroidism is also a harbinger of early heart failure (p 999) However the outlook in this disease is less serious because with the elimination of hyperthyroidism both the atrial fibrillation and heart failure usually disappear rapidly

Aside from its unfavorable implications established atrial fibrillation may itself contribute to an unfavorable prognosis The effect of the rapid ventricular rate and the loss of effective atrial contraction in impairing cardiac function and inducing heart failure have been mentioned On the other hand atrial fibrillation in a patient with heart failure may sometimes denote a better outlook than sinus rhythm and heart failure [4] For if the atrial fibrillation is replaced by sinus rhythm after quinidine therapy or after thyroidectomy in cases of hyperthyroidism the heart failure may likewise disappear Or if this is not possible slowing of the rapid ventricular rate by digitalis and rest usually effects a striking improvement These observations are applications of the general theorem that the outlook in heart failure is better if a causative factor can be found and eliminated than when there is no apparent remediable cause

TREATMENT

Digitalis quinidine and occasionally *procaine amide* are the drugs usually employed

The treatment of atrial fibrillation depends somewhat on whether this arrhythmia is established or paroxysmal and in the latter type whether an effort is being made to eliminate or to prevent the attacks. When paroxysmal atrial fibrillation is associated with a very rapid ventricular rate emergency treatment is indicated. Digitalization by the intravenous or oral route is swiftly effected. The use of quinidine or Pronestyl is considered *after the ventricular rate is slowed*. When atrial fibrillation is due to overt or masked hyperthyroidism sinus rhythm may be restored by correction of the hyperthyroidism with radioiodine,[4] thiouracil[illegible] or by subtotal thyroidectomy. Treatment may be unnecessary if there are no symptoms due to the arrhythmia or if paroxysms subside spontaneously after a very brief duration and recur infrequently. In general digitalis is indicated if there is evidence of circulatory insufficiency and preferred if there is significant underlying cardiac disease even without heart failure. Quinidine is usually given first choice if the arrhythmia is a symptomatic disturbance, is of recent duration and if there are no apparent heart disease, no significant cardiac enlargement and no heart failure. Quinidine is often employed when atrial fibrillation persists for more than a week after thyroidectomy for hyperthyroidism (p. 1012) or if it develops during mitral commissurotomy and persists for more than a week postoperatively. Pronestyl is most apt to be effective in paroxysmal atrial fibrillation.[3]

Sometimes, despite the usual contraindication in cases with heart failure, quinidine may be *employed with lifesaving effect after digitalis* and other therapeutic measures have failed.[8] Similarly in patients with repeated embolization, with and without heart failure, quinidine has been given when the outlook was poor and has been effective not only in restoring sinus rhythm but also in terminating the embolization and improving the circulation.[211] When the ventricular rate is slow due *to partial or complete heart block quinidine* is contraindicated.

The restoration of sinus rhythm appears important both because of the greater risk of arterial embolism when there is atrial fibrillation and because of the improvement in circulatory dynamics with sinus rhythm, especially in the cardiac response to exercise (p. 359). In recent years I have advocated that at least one vigorous attempt be made to convert virtually all cases of chronic atrial fibrillation to sinus rhythm with the aid of quinidine. Occasionally, arterial embolism occurs within 24 to 48 hours after conversion to sinus rhythm. It has appeared to me that the embolism took place not during conversion to sinus rhythm, but with recurrence of the atrial fibrillation. I have been greatly impressed by the simple fact that *arterial embolism occurs as a rule in patients* with atrial fibrillation especially with mitral stenosis and not in patients with sinus rhythm (except as a result of myocardial infarction with mural thrombosis, bacterial endocarditis or rarely a thrombus on an aortic arteriosclerotic plaque). No embolization occurred during or after successful conversion of atrial fibrillation to sinus rhythm by quinidine in 119 cases reported by Yount et al.,[illegible] in 93 cases reported by Sokolow[155] and 44 by McMillan and Welfare.[14] The risk of quinidine toxicity may be minimized by proper administration of the drug and observation of the patient and is greatly outweighed by the dangers of persistent atrial fibrillation. *Anticoagulants* have been employed for two weeks before attempting conversion of atrial fibrillation[17, 155] with quinidine or Pronestyl and for a variable period after conversion.

Digitalis Therapy in Atrial Fibrillation

The *purpose* of digitalis therapy in atrial fibrillation is to slow the ventricular rate, not to restore sinus rhythm. Most of the circulatory disadvantages of atrial fibrillation are due not to the irregularity but to the rapid ventricular rate. *Digitalis should be first administered* to slow the ventricular rate when this is rapid. Then conversion to sinus rhythm may be attempted with quinidine while digitalization is maintained. However, overdigitalization should be avoided as it may interfere with the effectiveness of quinidine.

The *action* of digitalis in atrial fibrillation may be as follows: 1. By stimulating the *vagus nerve it may foster atrial fibrillation*. According to the theory of repetitive impulses from an ectopic center, digitalis is ineffective in restoring sinus rhythm because it does not diminish and may enhance myocardial excitability. 2. By direct action on the a-v node and bundle digitalis slows conduction. This prevents most of the excessive atrial impulses from reaching the ventricle

allows more time for ventricular diastolic recovery and filling and results in slower more forceful ventricular contractions Thus the digitalis vagal effect tends to maintain the fibrillation of the atria while the direct effect on the functional conduction system slows the ventricular rate But the disadvantage of the former is more than compensated by the benefit of the latter

The *dosage and methods of administering digitalis* have been described elsewhere in detail (p 259) In occasional very urgent situations it may be advisable to administer digitalis intravenously (Figure 79) Rapid digitalization may also be accomplished by a single oral dose of digitalis glycoside The therapeutic effect and subsequent dosage should be gauged by the cardiac rate as determined by auscultation at the apex and not by examination of the pulse Serial electrocardiograms are desirable but rarely essential It is desirable to reduce the apical heart rate to between 60 and 70 per minute at rest This may not be possible in the presence of complications or associated conditions causing fever or in the presence of hyperthyroidism After the desired ventricular rate is attained the subsequent daily dose necessary to maintain this rate should be determined In instances of persistent atrial fibrillation it may be necessary to continue the maintenance dose of digitalis indefinitely

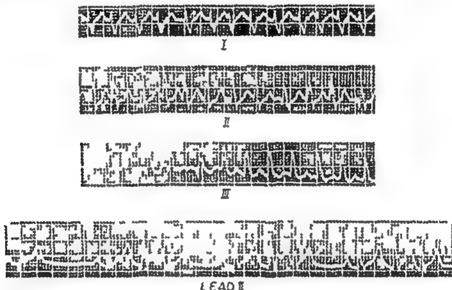
The *toxic symptoms* of digitalis have been discussed elsewhere (p 264) Attention is called again in particular to anorexia nausea and vomiting diarrhea yellow vision bigeminal rhythm multifocal (bidirectional) premature ventricular contractions and heart block Bradycardia of 50 or less or regular nodal rhythm developing during digitalis medication usually denotes excessive dosage

Quinidine Therapy (Fig 80)

The use of quinine for the treatment of cardiac irregularities was introduced in recent years by Wenckebach [76] Quinidine a dextro-rotatory isomer of quinine was later introduced by Frey [77] and found to be more effective

The *purpose* of quinidine therapy in atrial fibrillation is to restore normal sinus rhythm Quinidine therapy designed to convert atrial fibrillation to sinus rhythm is especially indicated when (a) there is a history of previous arterial embolism (b) there is intractable heart failure or (c) there are symptoms of anxiety or distress directly attributed to the arrhythmia

Complete heart block is an absolute contraindication and bundle branch block or severe intraventricular conduction disturbance [redacted] usually accepted as a contraindication to quinidine therapy [redacted] The contraindication to using quinidine in cases with bundle branch



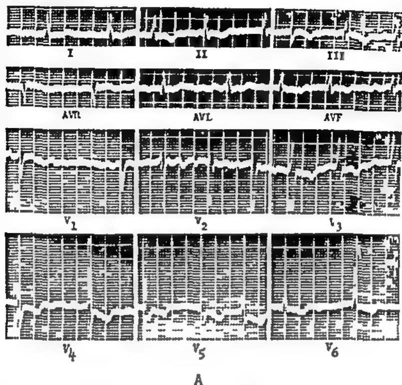


Fig 79 Paroxysmal atrial fibrillation in upper three strips Ventricular rate 210 per minute Lowest strip taken 1 hour after 0 8 mg of Cedilanid intravenously Sinus rhythm with trigeminy due to atrial extrasystoles

block is only relative since Goldman[87] reported the successful conversion of atrial fibrillation to sinus rhythm in 7 of 9 patients with bundle branch or intraventricular block. Many physicians have long regarded quinidine as not indicated or contraindicated in cases of chronic cardiac disease or heart failure, longstanding atrial fibrillation and cardiac enlargement, because of the tendency of atrial fibrillation to recur when it is abolished, because of the danger of embolization from atrial thrombi as sinus rhythm is restored, and because of the risk of sudden death from cardiac standstill.

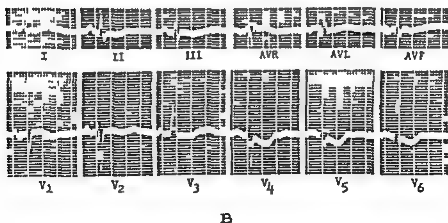

Fig 80 *A* Atrial fibrillation in a patient with mitral stenosis hypertension and recent cerebral embolism *B* Restoration of sinus rhythm after 2 gm of quinidine two days previously and 3 4 gm quinidine on preceding day

With increased understanding of the pharmacology and of the proper dosage and administration of the drug and with more objective control of dosage by direct writing electrocardiography and determinations of quinidine plasma levels these contraindi

cations have been greatly contracted and quinidine has been used more frequently to convert atrial fibrillation to regular sinus rhythm. Restoration of sinus rhythm has been variously reported in 50 to 89 per cent of cases or more.[156, 106, 188, 80, 189] Recently Brown and McMillan[30] reported restoration of sinus rhythm in 89 per cent of 67 patients with atrial fibrillation and congestive heart failure and virtually identical results were reported by Bedard.[14] A relapse occurred in 4 of 23 patients with rheumatic heart disease and in one of 35 patients with coronary heart disease. Sokolow[188] achieved restoration of sinus rhythm in 52 per cent of 94 cases of rheumatic heart disease and chronic atrial fibrillation and in 80 per cent of 85 non-rheumatic cases. In my experience the chances of success improve markedly in patients with rheumatic or coronary heart disease and enlarged hearts if the dosage of quinidine is increased to the point of moderate toxicity. Relapses most likely to occur in rheumatic heart disease should not exceed 20 per cent if adequate doses of quinidine are maintained.

The *action* of quinidine in atrial fibrillation is uncertain. The proposed explanation for the action of quinidine depends on one's advocacy of the circus movement theory or the theory of rapid impulses from ectopic foci as the mechanism of atrial fibrillation. According to the circus movement theory quinidine acts as follows in atrial fibrillation:

1. By direct action on the atrial musculature it prolongs the refractory period. Consequently, when the circus wave responsible for atrial fibrillation completes its circuit and finds the muscle still refractory, the circus movement is ended. This permits the sinoatrial node to reestablish itself as the pacemaker.

2. On the other hand, quinidine also slows the rate of impulse transmission (conduction). This tends to perpetuate the circus movement by allowing the tissue before the crest of the excitation wave more time to recover from its refractoriness. If the first effect (above) predominates, quinidine may abolish atrial fibrillation. If the second predominates, atrial fibrillation persists. The second effect also tends to slow the atrial rate. Consequently, atrial fibrillation is often converted to flutter before sinus rhythm is restored by quinidine.

According to the theory of rapid impulses from ectopic foci, the action of quinidine in atrial fibrillation is explained more simply.[1, 9] Quinidine depresses myocardial excitability and may lengthen the effective refractory period following contraction. It thereby diminishes the rate of impulse formation by an ectopic focus. When the rate is slowed to below the fibrillation threshold, atrial flutter usually ensues.[189] With further slowing or with inactivation of the focus, the sinoatrial node resumes its role as pacemaker. Success in converting atrial fibrillation to sinus rhythm is then determined on the one hand by the dose and plasma level of quinidine and on the other by the intensity of rapid impulse formation by the ectopic center. Failure to convert denotes inadequacy of quinidine dosage or excessive intensity of ectopic impulse formation. According to the circus movement theory, the success or failure of quinidine in restoring sinus rhythm is awkwardly attributed to predominant reduction in the refractory period when it succeeds and to predominant impairment in conductivity when it fails.

Quinidine tends to increase the ventricular rate, but this undesirable temporary effect is negligible if sinus rhythm is restored. The increased ventricular rate results from (a) the slowing of the atrial rate which allows better a-v conduction and (b) depression of the vagus nerve and therefore improved conduction of atrial impulses through the a-v node and bundle.

Thus quinidine is employed primarily in the hope that it will restore sinus rhythm by abolishing the ectopic focus or the circus rhythm. On the other hand, digitalis is employed with a view to slowing the ventricular rate by depressing a-v conduction; its effect on the atrial fibrillation, if any, is to foster it by shortening the refractory period or increasing atrial excitability.

Quinidine Plasma Levels. Recent studies have related proper dosage and administration of quinidine to quinidine blood plasma levels.[114, 190, 188, 8] Plasma quinidine concentration may be determined with the aid of the photofluorometer.[12] The control of arrhythmias is often dependent on attainment of a critical blood threshold level, which varies in different individuals but is reasonably constant in the same individual. The probability of controlling an arrhythmia increases

the higher the blood level. Therefore the dose of quinidine must be increased until the highest possible safe level as determined by symptoms, electrocardiographic signs and, if feasible, quinidine plasma concentrations, before conceding defeat in an effort to convert atrial fibrillation to sinus rhythm. However, in many patients restoration of sinus rhythm is accomplished with relatively small dosage and with plasma quinidine levels of 4 mg. per liter or less. Hence, dosage of quinidine should be raised gradually.

Following a single oral dose of 0.4 to 0.6 gm., quinidine is detected in the blood in one hour, usually reaches its peak in two or three hours and thereafter diminishes.[114] Approximately one-half the dose is dissipated in eight hours but some of the drug is still present after 24 hours. More than 90 per cent of the quinidine is usually eliminated in the urine in 24 hours. Since the peak concentration is usually attained in two hours, effective cumulation is accomplished by administering multiple doses orally every two hours. Furthermore, after five or six doses at two hour intervals—a common method of administration—about 40 to 50 per cent of the peak concentration is still present 12 hours after the last dose. Consequently, repetition of such a dose schedule on two or three successive days effects a progressive elevation of plasma quinidine level even without increase in the individual dose. Impaired renal function and severe congestive heart failure[11] may result in disproportionately high plasma quinidine concentration for a given dosage.

Often atrial fibrillation will be converted to regular sinus rhythm and sinus rhythm will be maintained when the plasma quinidine concentration ranges between 4 to 6 mg. per liter. This level can usually be attained by doses of 0.4 to 0.6 gm. four times daily. Sokolow[113] was successful in converting atrial fibrillation to sinus rhythm in 82 per cent of 119 attempts in 111 patients with a mean plasma quinidine level of 5.4 mg. per liter (usual range 4 to 8 mg. per liter) on a regimen of 0.4 to 0.6 gm. every two hours for five doses daily. However, persistent atrial fibrillation often cannot be converted until the plasma level reaches 8 to 10 mg. per liter. Thereafter, sinus rhythm may be maintained with lower quinidine concentrations. Vomiting, diarrhea, mild tinnitus and mild prolongation of intraventricular conduction may occur at blood levels between 4 and 6 mg. per liter but serious toxic disturbances are infrequent unless the plasma concentration exceeds 8 or 9 mg. per liter.

Administration of Quinidine in Atrial Fibrillation

Oral Administration. One or two doses of 0.2 gm. (3 grains) each may be given an hour apart to test for sensitivity. This is done as a matter of custom; its value is uncertain. Subsequent dosage has not become standardized since occasional patients experience a favorable response with one or two small doses while others require the maximal dosage that can be tolerated. As a rule I prescribe 0.3 gm. (5 grains) every two hours for six to eight doses, discontinuing when the patient is asleep at night. This dosage is repeated the following day if the arrhythmia persists. Thereafter, if unsuccessful and if there are no toxic symptoms (see below, p. 369), I increase the dosage progressively (0.4 gm. every two hours for six doses the following day, then 0.6 gm. every two hours for five doses the next day, and finally 0.8 gm. every two hours for five doses if tolerated). If this fails it is rarely desirable or effective to exceed 4 gm. daily. In fact, if 0.6 gm. every two hours for six doses do not restore sinus rhythm, larger doses rarely succeed.[7] When more than 2 gm. daily is given, serial electrocardiograms should be taken to observe whether excessive prolongation of intraventricular conduction occurs due to quinidine toxicity. As a rule, toxic symptoms appear when more than 3.0 gm. is given daily and it is difficult to increase the dose beyond 4 gm. daily because of toxic symptoms or signs.

Many variations of the above schedule may be followed. One may also administer 0.4 gm. of quinidine every four hours day and night for two to four days until sinus rhythm is restored or significant toxicity is evident. This mode of administration may be improved by the use of delayed absorption coated pills taken at bedtime to eliminate the need for a dose during the sleeping hours.[171] Another method is to give 0.2 or 0.4 gm. of quinidine four times daily for 72 hours. If this is ineffective, the dose is increased by 0.2 gm. every 72 hours. Thus if one begins with 0.4 gm. four times daily, the patient receives 0.6 gm. four times daily by the fourth day, 0.8 gm. four times daily by the seventh day, and so on. In mild arrhythmias 0.3 gm. (5 grains) three or four times daily may suffice. Occasionally a

single large daily dose is effective when multiple doses at regular intervals are not. In the series reported by Brown and McMillan[20] in which conversion to sinus rhythm was effected in 89 per cent of cases, the average total dose of quinidine was 2.8 gm (range 1.8 to 4.2 gm) in patients with rheumatic heart disease and 2.5 gm (1.2 to 5.4 gm) in patients with atherosclerotic heart disease.

Sometimes it becomes necessary to discontinue quinidine before atrial fibrillation has been converted to regular sinus rhythm. But it should be emphasized that a high percentage of success will be attained only at the expense of moderate toxicity in many patients. Tolerable nausea and vomiting, slight tinnitus and slight degrees of widening of the QRS complex are not necessarily contraindications to further doses of the drug. The drug should be discontinued if the QRS complex is widened to 0.14 second or more, if the P wave disappears or there are frequent ventricular premature beats or ventricular tachycardia, or if there are other evidences of toxicity listed below. It should also be discontinued if the quinidine plasma concentration is more than [illegible] mg per liter.

Note that a given regimen of quinidine administration may fail at one time, yet succeed at a later day. Marked nervous tension, infection or fever from any cause, pulmonary or myocardial infarction, digitalis toxicity and severe heart failure are among the factors which have been noted to interfere with the effectiveness of quinidine. When time or treatment have controlled these inhibiting factors, a course of quinidine should be repeated and this will often succeed despite previous failure.

Maintenance of Quinidine. When regular sinus rhythm is established, maintenance doses of quinidine are continued, usually beginning with 0.4 gm four times daily. McMillan and Welfare[14] found the average maintenance dose 0.28 gm every six hours. Larger or smaller doses are given according to the dose required for conversion. If sinus rhythm persists for several months, the maintenance dose may be gradually reduced and even discontinued eventually. If there is a recurrence of atrial fibrillation, conversion may be attempted by the original doses which were effective.

Intravenous Administration of Quinidine. Very rarely the urgency of a situation may demand that quinidine be given parenterally, e.g., in some cases of ventricular tachycardia.

Quinidine gluconate is available in 10 cc rubber stoppered ampules containing 0.8 gm of the quinidine salt or 0.5 gm of the anhydrous quinidine. This is administered intravenously very slowly until the desired effect is obtained. The usual dose is 0.3 to 0.8 gm (4 to 10 cc). Greater safety and better control of dosage are obtained by diluting the ampule of quinidine gluconate in 50 to 150 cc of 5 per cent glucose solution and administering the solution at about 2 to 5 cc (25 mg) per minute. Frequent electrocardiograms should be taken during the infusions.

Quinidine hydrochloride (Brewer) is available in 2 cc ampules containing 0.6 gm for intravenous or intramuscular use. *Quinidine lactate* (Lilly) is also supplied in ampules of 0.65 gm dissolved in 10 cc of sterile saline.

Intramuscular Administration of Quinidine. Quinidine gluconate may be effectively employed by intramuscular administration. Since a definite response may be obtained in 15 minutes or less and a maximum effect in 1 to 2 hours, intramuscular administration is preferable to intravenous, even when speed is important, except in the most urgent situations. Intramuscular quinidine is also indicated when the patient is unable to take oral medication or absorption is uncertain, i.e., in the presence of intense nausea, vomiting, diarrhea, stupor or shock. Five cc (0.4 gm) of the quinidine gluconate is administered intramuscularly and may be repeated once or twice at two to four hour intervals until the desired effect is obtained or toxic manifestations compel discontinuation.

Quinidine is also indicated in the treatment or prevention of various types of premature beats (p. 341), atrial flutter (p. 357), atrial tachycardia (p. 350) and ventricular tachycardia (p. 374), except when the latter is associated with Adams-Stokes syndrome.

Toxic Effects of Quinidine. Quinidine is a toxic and sometimes dangerous drug which must be administered with special care. It is therefore advisable that the patient be under close supervision. If large doses are given, serial electrocardiograms are desirable.

Among the *toxic symptoms* are those known as cinchonism, caused not only by the cinchona alkaloids but also by salicylates and cinchophen. These symptoms with mild intoxication include tinnitus, impaired hearing

headache, nausea, mild diarrhea or a slight disturbance in vision. Vomiting, diarrhea and slight tinnitus are the commonest symptoms with effective quinidine dosage. With more advanced toxicity, tinnitus and hearing impairment become more severe; there is a blurring of vision, disturbed color perception, photophobia and diplopia (quinine amblyopia or amaurosis);[16] nausea, vomiting, diarrhea and abdominal pain are frequent; the skin becomes hot and flushed and urticarial, macular or papular eruptions occur. Severe cerebral symptoms may develop, ranging from headache to fever, confusion and delirium. I have observed a patient in whom a single dose of quinidine given orally was followed on several occasions by chills and fever within two hours and then by purpura and melena. Fever[17, 191] or thrombocytopenic purpura[16, 195] due to quinidine has since been reported by various observers.

Respiratory distress, cyanosis, dizziness and cold sweat, convulsions and collapse may result from quinidine idiosyncrasy.[19] Convulsions may result from direct action on the cerebral cortex or from the production of cardiac asystole but are extremely rare.

A serious *tachycardia* associated with atrial flutter may follow treatment of atrial fibrillation by quinidine. This is less likely to occur if quinidine is given after previous digitalization.

Electrocardiographic Changes and Cardiac Complications of Quinidine. *Intraventricular conduction defect* with widening of the QRS to more than 0.12 second, cardiac standstill, ventricular tachycardia[209] and ventricular *fibrillation*[9] *may result from the depressant* effects of quinidine on the cardiac musculature and conduction system. A prolongation of the Q-T interval occurs early and increases with augmented dosage. However, this does not necessarily indicate toxicity. The prolonged Q-T interval may be due to a prominent U wave, widening of the QRS or both.[298] Depression of the ST segment, low voltage of T waves, widening and notching of the P wave are other electrocardiographic changes which may occur *even with therapeutic doses of* quinidine. Atrioventricular and bundle branch block are common with toxic doses. Marked widening of the QRS to 0.16 to 0.20 second or more may presage impending ventricular tachycardia or fibrillation. Sudden death following quinidine therapy is more apt to be due to cardiac standstill (depression of the sino-atrial and a-v nodes) or to ventricular tachycardia and ventricular fibrillation[9, 1] than to embolization. It may also result from respiratory paralysis. When collapse follows quinidine, revival of the heart is most apt to be effected by the administration of epinephrine or norepinephrine.[71]

All these symptoms and signs should be excluded by careful questioning and examination *before each new dose of the drug is given*. Serial electrocardiograms should be taken when large doses of quinidine are given or when the drug is administered for long periods. Occasionally, mild symptoms may have to be tolerated if the arrhythmia is sufficiently disturbing and is controlled only by *slightly* toxic doses of quinidine. Otherwise the drug should be discontinued when symptoms of intoxication are discovered.

Treatment of Atrial Fibrillation with Procaine Amide (Pronestyl)

Procaine amide (p. 340) is effective in converting many cases of atrial fibrillation to sinus rhythm[176, 166, 173, 67] and should be employed if quinidine cannot be tolerated or is ineffective. Schack and associates[173] restored sinus rhythm in 17 of 21 patients with atrial fibrillation of less than one week's duration, in 15 of 25 patients with atrial fibrillation for more than one week but less than three years, but in only 3 of 15 patients with the arrhythmia for more than three years. Digitalization is first instituted to slow the ventricular rate. Then 1 gm. (4 capsules) of the procaine amide is given orally every three or four hours for six doses or until sinus rhythm is restored. *Usually a total of 3 to 6 gm. are required*. If this dose is ineffective, it is improbable that conversion to sinus rhythm will be accomplished. Procaine amide may also be administered intramuscularly or intravenously in 500 to 2000 mg. doses (p. 375).

Maintenance therapy consists of 0.5 gm. orally every six hours. Attempts may be made to reduce and discontinue the drug after two or more weeks of sinus rhythm. Toxic effects (*see also p. 341*) *include electrocardiographic* changes (such as lowering of the voltage of QRS and T waves, widening of QRS and QT), nausea, vomiting, choking sensations, diaphoresis, malaise or prostration.

Anticoagulant Therapy

Oral anticoagulants (p. 577) may be uti-

lized for a period of two weeks prior to the employment of quinidine or Pronestyl and for a variable period thereafter in an effort to prevent embolization due to changing rhythm Oral anticoagulant therapy for prolonged periods has also been advocated in patients with atrial fibrillation and emboli, even when no effort is made to convert the arrhythmia to sinus rhythm Claims that the incidence of embolism is reduced[48] are difficult to evaluate

Treatment of Paroxysms

Treatment of a paroxysm of atrial fibrillation is indicated only if it is associated with distressing and prolonged palpitation evidences of heart failure or of cerebral or peripheral ischemia Specific treatment is usually unnecessary when symptoms are mild or absent when the attack is of very brief duration or when it is symptomatic of some underlying disease such as hyperthyroidism pneumonia surgical procedures etc In the latter circumstances treatment is directed only to the underlying disease for the arrhythmia subsides spontaneously or with cure of the basic cause

When specific treatment of the arrhythmia is necessary digitalis quinidine or procaine amide (Pronestyl) may be administered as described above for established atrial fibrillation As a rule I first digitalize the patient rapidly to slow the ventricular rate Often sinus rhythm reappears very soon even before quinidine is started Otherwise I administer quinidine or if this is not readily effective I employ Pronestyl orally Pronestyl has been found to be more effective in paroxysmal than in established atrial fibrillation (For dosage and methods of administration see digitalis p 259 quinidine p 368 and procaine amide (p 340) Atabrine (0 4 gm intramuscularly) may be tried if these fail [83, 37]

Prevention of Attacks

Quinidine is usually employed to prevent attacks of atrial fibrillation which recur frequently and produce distressing symptoms It is impractical to take this drug continuously when attacks occur rarely When indicated the quinidine may be given in doses of 0 2 gm (3 grains) three times daily and increased progressively in dosage and frequency until the attacks no longer recur or symptoms of toxicity appear But it is rarely justifiable to take more than a maximum of 3 gm daily (divided in six to twelve doses) If the patient discovers that the attacks occur at definite times during the day or night or under special circumstances, a dose of quinidine sulfate 0 2 to 0 4 gm (3 to 6 grains) may be taken one to two hours prior to the time the attack is anticipated Such extra doses at critical times may be used also to supplement the regular schedule of quinidine Long acting quinidine tablets taken before retiring are useful to prevent nocturnal attacks

If quinidine proves ineffective in preventing frequent and annoying paroxysms the patient should be digitalized (p 259) and kept on maintenance doses of digitalis This regime is designed not to prevent attacks but to restrain the ventricular rate to below 100 per minute if and when the attack should recur However this objective is not usually attained

VENTRICULAR TACHYCARDIA

Ventricular tachycardia is a rapid regular rhythm in response to stimuli arising in an ectopic focus or ring in the ventricular conduction system [80] Usually the tachycardia occurs in brief paroxysms lasting minutes or hours but occasionally it persists for weeks or months (Dubbs and Parmet [81] 21 days Freundlich [74] 26 days May [135] 77 days) Gallavardin[83] has described a form of ventricular tachycardia recurring in very brief paroxysms and characterized by runs of ventricular extrasystoles separated by one two or several sinus beats

Mechanism

The mechanism of ventricular tachycardia is probably similar to that of atrial tachycardia (p 344) except that the ectopic focus or ring is situated in the ventricle instead of in the atrium The tachycardia is then visualized as a series of rapid rhythmic premature beats arising in this ectopic focus or in response to a similar series of circus movements in a ventricular ring of tissue [82]

Experimentally ventricular tachycardia has been produced by ligation of a coronary artery by the administration of barium chloride by application of aconitine [175] by electrical stimulation[151] and by combined stimulation of the vagus and accelerator nerves [143] Chloroform and cyclopropane anesthesia predispose to the production of ventricular tachycardia by epinephrine [107, 111]

The ventricular rate varies usually between

150 and 250 but may be as rapid as 300 per minute. Sometimes the atria contract regularly and independently in response to the normal sinus impulse while the ventricles respond to the ectopic ventricular stimulus. However, the atria may also respond to the ventricular stimulus which may be conducted backward (retrograde conduction) along the bundle branches, a-v bundle and node. Since retrograde conduction is more difficult than normal downward conduction along the bundle and since the rate of ventricular impulse formation is excessive, various degrees of ventricular-atrial block may occur. In this respect ventricular tachycardia resembles atrial flutter with a reversal in origin and direction of the controlling impulse.

The Electrocardiogram

The electrocardiogram of ventricular tachycardia is characterized by (Figs. 81, 82):

1. *QRS complexes with approximately regular rhythm which are slurred and widened at rates of 150 to 200 or more per minute.* The configuration of the QRS is that of a left or right ventricular premature beat, or the complexes may be alternatingly bidirectional. The latter is most often associated with digitalis intoxication[2,4,100] and severe myocardial damage. The change in direction has been attributed to cardiac control by two independent ventricular foci or to a single ectopic impulse, possibly at the bifurcation of the bundle of His, which is transmitted alternately over the left and right bundle branches because of a defect in conduction. Before and after the paroxysm one may find isolated ectopic ventricular complexes with the same form as that seen during the paroxysm.

2. The P waves are usually undisturbed in their sinus rhythm but are often obscured by the ventricular complexes. Esophageal or right precordial leads may disclose the P waves at a slower rate than ventricular systoles. When 1:1 retrograde conduction occurs, the P waves may be observed abnormal in contour and superimposed on the T waves or following them. P waves are often less frequent than QRS complexes owing to retrograde partial heart block (dropped atrial beats).

Fig. 81. Paroxysmal ventricular tachycardia. Lead I. A brief paroxysm preceded and followed by sinus beats. Abnormal configuration QRS complexes denoting ectopic focus but all from same site. Slower rate and slight irregularity of R-R cycles in contrast with regularity in atrial tachycardias.

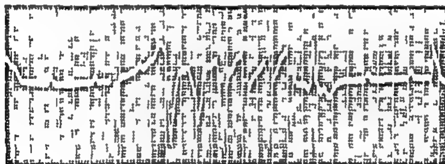

Fig. 82. Ventricular tachycardia in complete heart block associated with Adams-Stokes syndrome. Attacks accentuated by administration of epinephrine.

Occasionally atrial fibrillation or atrial tachycardia accompanies paroxysmal ventricular tachycardia but this must be distinguished from atrial flutter or fibrillation with bundle branch block. Ventricular tachycardia may be associated with a-v dissociation or complete heart block.

Following subsidence of a paroxysm of ventricular tachycardia the T waves may be inverted for a few hours or days, possibly due

to myocardial fatigue or ischemia occasioned by the tachycardia [194] The electrocardiographic pattern seen after a paroxysm of ventricular tachycardia may closely simulate that of acute myocardial infarction [74] This similarity is heightened when the paroxysmal tachycardia is accompanied by intense precordial oppression or pain The differentiation can usually be made by a consideration of the history and ancillary clinical findings (Chapter 21)

Occasionally the electrocardiogram of ventricular tachycardia may be confused with that of atrial tachycardia and intraventricular conduction disturbance or with atrial flutter and 1 1 block or with atrial fibrillation with aberrant ventricular complexes [1, 196] Ventricular tachycardia may be distinguished in a long strip of the electrocardiogram by the finding of isolated premature ventricular beats with the same QRS configuration before or after the paroxysm or by the discovery of P waves in abnormal relationship to the QRS complex and at a slower rate or by the occurrence of occasional transitional ventricular complexes resembling sinoatrial beats [80]

Ventricular flutter is characterized by rapid uniform and virtually regular oscillations usually at the rate of 250 per minute or more The complexes differ from those of ventricular tachycardia in the absence of distinct QRS and T waves or a blending of the two in ventricular flutter The latter is distinguished from ventricular fibrillation in that the undulations are irregular in size shape and rhythm

Etiology

Paroxysmal ventricular tachycardia is most often associated with recent myocardial infarction but it may occur also with hypertensive and coronary heart disease or rheumatic heart disease It has followed the administration of excessive amounts of digitalis [75] quinidine [69] or Pronestyl and has resulted from potassium intoxication [1, 5] *Ventricular tachycardia due to digitalis may be* characterized by bidirectional ventricular complexes [274, 100] A relationship of ventricular tachycardia to emotional strain and fatigue has been postulated [18] Ventricular tachycardia may occur without apparent organic heart disease In a review of 107 cases of paroxysmal ventricular tachycardia Armbrust and Levine[7] noted that the arrhythmia was associated with coronary heart disease in 74 per cent with rheumatic heart disease in 8 4 per cent and with apparently normal hearts in 12 per cent Furthermore there were 5 instances of serious or fatal paroxysmal ventricular tachycardia complicating the W-P W syndrome But these may have represented instances of atrial tachycardia or fibrillation with conduction through an anomalous atrioventricular bundle Wilson et al [217] described a clinical type of ventricular tachycardia apparently induced by exertion Orthostatic paroxysmal ventricular tachycardia has also been described [188]

Ventricular tachycardia as well as other arrhythmias occurs relatively frequently in the course of human cardiac catheterization[88] and surgical operations especially those involving manipulation of the heart and great vessels But they appear also in the course of various thoracic or other operations [110, 35] The arrhythmias occur not only because of direct mechanical cardiac irritation but also as a result of anoxia and vagal reflexes associated with the anesthesia and the operation

Symptoms and Signs

The variable clinical forms of ventricular tachycardia have been classified by Froment et al [71] into a number of categories including (1) terminal prefibrillatory tachycardia occurring in association with serious underlying disease and always fatal (2) ventricular paroxysmal tachycardia due to lesions of the septum caused by coronary occlusion or syphilis (3) less serious forms of ventricular tachycardia in apparently healthy hearts The subjective symptoms are identical with those described under atrial paroxysmal tachycardia (p 346) Essentially these are attacks of palpitation starting and stopping suddenly lasting from a few minutes to many hours with mild to moderate dyspnea and occasionally dizziness faintness or syncope due to cerebral ischemia caused by a deficient cardiac output Occasionally there is little or no subjective distress even when as in a case described by Freundlich [76] the tachycardia persisted for 26 days

Paroxysmal ventricular tachycardia occurring in patients with heart block may be complicated by ventricular fibrillation ventricular arrest and the Adams Stokes syndrome [1, 157] (Fig 83) Not infrequently substernal and precordial pain identical with that of angina pectoris may appear at the onset of the tachycardia When the pain is

severe and persistent, it closely resembles that of acute myocardial infarction When ventricular tachycardia complicates acute myocardial infarction it is often associated with the clinical picture of shock Congestive heart failure is likely to occur with ventricular tachycardia especially if the attack is prolonged and there is serious underlying heart disease

Examination discloses an apical and pulse rate of 160 to 180 but occasionally as high as 200 to 300 per minute Although the rhythm is regular prolonged auscultation of the heart may disclose slight irregularity as well as corresponding differences in the quality or intensity of the first sound[197] (But cf. also MacKinnon[198]) The latter is due to varying relationships of the atrial and ventricular contractions in different cycles and therefore to differences in the position of the atrioventricular valve cusps which determine the character of the first heart sound Occasionally only one heart sound is heard with each beat

The jugular veins may, as in atrial tachycardia, show prominent regurgitation ("a") waves due to the occurrence of atrial contraction, while the tricuspid valve is closed by simultaneous ventricular systole There are fewer jugular pulsations than apical heart beats

Other symptoms and signs often present are due to an underlying acute myocardial infarction, to digitalis intoxication or to the heart failure which necessitated the use of digitalis

Diagnosis

For diagnosis and differential diagnosis of the tachycardias, see page 378

Prognosis

Ventricular tachycardia, unlike atrial tachycardia, is usually a serious condition, partly because of the frequency of an underlying myocardial infarction and partly because it may be the harbinger of a fatal ventricular fibrillation Ventricular tachycardia with alternating direction of the ventricular complexes has been considered especially ominous and almost invariably fatal But recoveries have been observed with appropriate treatment whether the direction was unidirectional or bidirectional[16] Zimmerman[203] treated 8 of 10 cases of ventricular tachycardia with quinidine with recovery in 7 of them Ventricular tachycardia may persist for many days or weeks[204] In general the prognosis of ventricular tachycardia, as of most arrhythmias depends on the absence or presence of underlying cardiac disease and on the outlook presented by that disease The prognosis is generally favorable in those without apparent heart disease

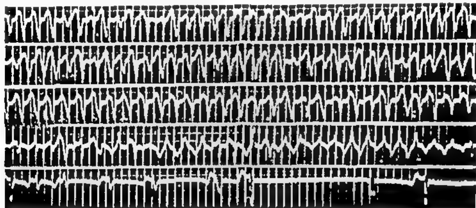

Fig 83 Ventricular tachycardia followed by prolonged ventricular standstill and Adams-Stokes syndrome

Treatment

Quinidine and procaine amide are the most effective drug Both depress myocardial excitability They are both contraindicated when ventricular tachycardia is associated with heart block and Adams-Stokes syndrome Under these circumstances Isuprel should be administered subcutaneously[115] or sublingually[181] (p 393)

Quinidine in Ventricular Tachycardia Quinidine effectively restores normal rhythm in the majority of cases For details of quinidine administration see page 368 Oral administration is preferred except in extreme emergency, the dosage is that which accomplishes the desired result without serious toxicity Commonly,

after a test dose of 0.2 gm. (3 grains) 0.3 gm. is administered every 2 hours for 6 doses. This dose is increased daily to 0.4 gm., etc., as described under atrial fibrillation (p. 368). Maintenance doses, varying from 0.3 gm. (5 grains) three times daily to 0.6 gm. four or five times daily, may be required for several days or longer to prevent a recurrence.

Occasionally quinidine must be given intravenously[41, 109] or intramuscularly for extreme emergency or urgent haste, or because the patient is vomiting and unable to take oral medication. Quinidine gluconate, lactate or hydrochloride may be employed for intravenous or intramuscular injection. Quinidine gluconate is administered very slowly intravenously until sinus rhythm is restored or toxic effects appear or up to a total of 0.8 gm. (10 cc.). Or the 10 cc. ampule may be diluted in 50 to 150 cc. of 5 per cent glucose in distilled water and given by slow drip in 30 minutes to an hour. Quinidine gluconate may also be given intramuscularly (0.4 to 0.8 gm., i.e., 5 cc. to 10 cc.) and repeated several times if necessary at two hour intervals. Frequent electrocardiograms are desirable to avoid toxic effects and to evaluate the effectiveness of quinidine therapy.

Procaine Amide (Pronestyl) in Ventricular Tachycardia[115, 185, 4] Pronestyl is as effective as quinidine in the treatment of ventricular tachycardia and may be preferable to quinidine when the urgency of the situation indicates the need for intravenous administration, or when the ventricular tachycardia is due to digitalis toxicity. Pronestyl may be effective after quinidine has failed[108] and vice versa. The usual recommended intravenous dose is 100 to 200 mg. per minute up to a total of 2 gm., but the possibility of hypotension may be minimized by even slower administration, e.g., at the rate of 100 mg. in five minutes, with frequent determinations of the blood pressure. For slow intravenous infusion 1 or 2 gm. of procaine amide is dissolved in 100 or 200 cc. of 5 per cent glucose in distilled water and administered at the rate of 2 to 3 cc. per minute. As with quinidine, concomitant electrocardiographic observations are desirable. All of seventeen episodes of persistent paroxysmal ventricular tachycardia in 13 patients treated with Pronestyl intravenously were terminated by doses ranging from 300 to 2500 mg.[114] Seven of these required more than 1000 mg. The intravenous infusion is discontinued as soon as regular sinus rhythm is restored or if marked widening of the QRS or P-R interval appears.

The most serious complications of intravenous Pronestyl therapy are marked widening of the QRS complexes, convulsions and hypotension.[193] The hypotension may be combated by slowing or stopping the injection, or by administering norepinephrine (Levophed) intravenously[179] (p. 563). The administration of 100 mg. of phenobarbital sodium intramuscularly before starting the intravenous Pronestyl has been advocated to prevent possible convulsions.[154]

Procaine amide is also rapidly effective when administered *intramuscularly* and usually obviates the need for intravenous injection. Peak levels of Pronestyl may be attained within fifteen minutes to an hour.

The intramuscular dose of Pronestyl is 0.5 to 1.0 gm. (5 to 10 cc.) initially. It may be repeated every two or three hours for several doses if the previous doses are ineffective.

Procaine amide may be given orally if there is no urgency. One gram (4 capsules) is given initially and repeated in two hours. If sinus rhythm is not restored, 0.5 to 1.0 gm. may be given thereafter at four to six hour intervals. A maintenance dose of 0.5 gm. every four hours may be desirable to prevent recurrence. The toxic effects of Pronestyl have been discussed (p. 341).

Other measures have been successfully employed to stop attacks of ventricular (and atrial) paroxysmal tachycardia. *Magnesium sulfate* in 20 per cent solution may be given intravenously, the first 5 cc. very slowly and then an additional 5 to 10 cc. if there are no ill effects and if the arrhythmia persists.[8, 100] *Calcium chloride* or *gluconate* has been reported to be effective when given intravenously in 10 per cent solution (10 to 20 cc. equals 1 to 2 gm.). *Potassium salts* (the chloride, acetate or iodide) have been given orally in doses of 1 to 5 gm. (15 to 75 grains) two to six times daily to decrease the frequency of attacks,[170] especially when ventricular tachycardia is due to digitalis toxicity. In one case in which the arrhythmia failed to respond to all of the above measures, sinus rhythm was restored and heart failure eliminated following the intramuscular injection of 0.4 gm. of atabrine. Samia and Alimuring[183] more recently reported a similar experience with a case of ventricular tachy-

cardia unresponsive to Pronestyl and quinidine in which sinus rhythm was restored after five oral doses of quinidine 0.3 gm each at two hour intervals. The intravenous injection of 10 to 20 mg of morphine sulfate repeated if necessary in a half to two hours has been advocated.

Although digitalis has generally been regarded as contraindicated in ventricular tachycardia, benefit has been reported when the drug was employed in cases not associated with digitalis toxicity or myocardial infarction. Digitalis may be dangerous in ventricular tachycardia complicating acute myocardial infarction because of increased myocardial irritability and the consequent hazard of inducing ventricular fibrillation.[69]

VENTRICULAR FIBRILLATION

Ventricular fibrillation is an extreme arrhythmia characterized by rapid irregular uncoordinated and ineffective twitchings of the ventricles.

In animals ventricular fibrillation may be induced by electrical stimulation (faradization) as was first demonstrated in Ludwig's laboratory in 1850.[104] But it may also be induced experimentally by coronary artery ligation, mechanical irritation, drugs such as barium chloride, calcium chloride, digitalis or epinephrine in excessive dosage. Chloroform and cyclopropane anesthesia are predisposing factors. It will be noted that many of these factors have been mentioned as capable of producing ventricular tachycardia. In fact ventricular premature beats, ventricular tachycardia and ventricular fibrillation are not an uncommon sequence in both experimental and human fibrillation of the ventricles.

Mechanism

The responsible mechanism, as in atrial fibrillation, is either an irregular or inconstant circus movement or an ectopic focus or foci with very rapid repetitive stimuli. According to Wiggers[1, 213] fibrillation starts with a premature beat from an ectopic focus or ring in the ventricle and is followed by circus movements involving smaller and smaller rings of myocardium, each of which develops independent excitations. This produces relatively ineffectual fractionate muscular contractions which become weaker and weaker as the coronary blood flow diminishes. The circulatory effects of ventricular fibrillation are much more serious than those of atrial fibrillation, for cardiac contraction becomes so ineffective that it is tantamount to asystole. The stroke output is annihilated and syncope and death follow.

The Electrocardiogram

The electrocardiogram exhibits rapid regular or irregular oscillations representing bizarre QRS complexes (Fig. 84). One type of

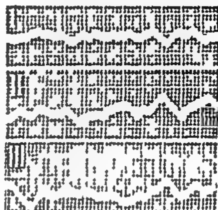

Fig. 84. Ventricular fibrillation in a fatal paroxysm of Adams-Stokes syndrome.

oscillation is fairly uniform with an amplitude of 8 to 10 mm. and a frequency of 130 to 300 per minute, which may gradually diminish as asphyxia develops.[11] This type has no isoelectric interval and is sometimes called ventricular flutter. In a second type the oscillations are irregular, somewhat more rapid and vary in amplitude (from 3 to 18 mm.), width and configuration. Terminally, ventricular fibrillation is characterized by completely irregular waves of low voltage or mere irregular undulations. There is usually complete or partial heart block and established a-v dissociation, or there may be sinus rhythm. In any event the atria continue their regular rhythm and usual rate until asphyxia develops.

The attack of ventricular fibrillation is usually introduced by an acceleration of the basic ventricular rhythm, always by "initial" premature beats, and often by short runs of irregular ventricular oscillations.[11] Impending ventricular fibrillation may be suggested by prefibrillatory phenomena characterized successively by (a) a labile basic ventricular rate, (b) the appearance of premature ventricular beats singly and in groups and (c) the appearance of bizarre ventricular com

plexes.[154] During the attacks there may be short or long asystolic pauses followed by a recurrence of the irregular rhythm of fibrillation or a return to the dominant rhythm (usually sinus rhythm with heart block) with occasional ventricular premature beats.

Etiology

In humans ventricular fibrillation may occur following acute cardiac infarction, in the course of heart block with Adams-Stokes syndrome, during surgical procedures under general anesthesia, following electrocution or lightning shock, after toxic doses of digitalis,[illegible] acetylstrophanthidin,[illegible] quinidine or Pronestyl, or as a terminal event in a variety of diseases usually after a more or less brief period of ventricular tachycardia. Since ventricular fibrillation is discovered accidentally and only by means of the electrocardiograph, it is uncertain how many unexplained and sudden deaths result from ventricular fibrillation.[196] Although the available experimental and clinical observations indicate that myocardial anoxia or necrosis[96] or certain toxic disturbances are chiefly responsible for initiating ventricular fibrillation, the exact mechanism is uncertain.

Clinical Aspects

Ventricular fibrillation is usually viewed as a terminal and terminating incident in certain instances of sudden death listed above under etiology, in all of which there may be insufficient anatomic change to account for the fatality. Ventricular fibrillation may also occur as a terminal incident in diseases which in themselves represent adequate causes of death.

Of more practical importance are the cases in which ventricular fibrillation is not soon fatal but occurs in transient paroxysms from which the patient recovers for a variable period of time. I have seen several patients suffer such attacks over a period of months, while another experienced innumerable ones over a period of 48 hours. Recovery from ventricular fibrillation following acute coronary occlusion has been reported.[51] Recovery may occur after absence of the heart beat for as long as five minutes.

These paroxysms are exhibited clinically as attacks of Adams-Stokes syndrome (p. 390) with syncope and convulsions indistinguishable from those due to ventricular standstill.[18] The fruitless ventricular twitches without mechanical expulsion of blood result in periods of asystole which are identical in effect with those due to ventricular standstill. Faintness occurs when ventricular fibrillation lasts 3 seconds or more, syncope after 10 to 20 seconds, and convulsions, apnea and incontinence after 40 seconds (average figures).

Treatment

When ventricular fibrillation is characterized by virtual asystole, sudden disappearance of heart sounds and blood pressure, treatment is that discussed under cardiac arrest (p. 1110). Essentially it consists of immediate thoracotomy, defibrillation[illegible] and restoration of the heart beat by cardiac massage. Oxygenation of the heart is maintained by cardiac massage and artificial respiration until the heart can be defibrillated. Ventricular fibrillation lasting for at least ten minutes has been abolished by electric shock.[17] Mouth to mouth breathing is carried out or oxygenation is maintained by a mechanically controlled respiration supplying 100 per cent oxygen under pressure. During this artificial respiration an alternating current is passed momentarily through two electrodes placed on the anterior and posterior aspect of the heart, in the form of one or more shocks at one second intervals ("serial defibrillation").[illegible] The development of a combined external cardiac pacemaker and defibrillator gives promise of carrying out both defibrillation and resumption of cardiac contraction without thoracotomy.[164]

When ventricular fibrillation occurs in transient paroxysms and when sinus rhythm is known to have been present before or between the paroxysms, Pronestyl or quinidine may be administered intravenously or intramuscularly as described above (p. 375). But quinidine and Pronestyl are contraindicated when the ventricular fibrillation occurs in patients with complete heart block and Adams-Stokes syndrome[188] (p. 393). In such cases the drug of choice is probably Isuprel (isopropylnorepinephrine)[150, 161] which is administered sublingually in 15 mg. doses every two hours or as required to control and prevent the attacks. It may also be administered subcutaneously in doses of 0.2 mg. Hydroxyamphetamine (Paredrine) in doses of 20 to 60 mg. every two to four hours orally may be used to prevent recurrence of the attacks.[150]

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS OF TACHYCARDIAS

Regular Tachycardias

The tachycardias may first be segregated according to whether the rhythm is regular or irregular. If regular, the tachycardia may be sinus tachycardia, atrial, nodal or ventricular paroxysmal tachycardia or atrial flutter. A sudden onset and cessation of palpitation and tachycardia and the history of similar paroxysms is characteristic of the paroxysmal tachycardias and flutter but not of sinus tachycardia. If the heart rate exceeds 160 and especially if it is between 180 and 200 per minute, the disorder is usually a paroxysmal tachycardia, most commonly atrial. Sinus tachycardia and atrial flutter are associated with rates below 160 per minute, although the latter usually exceed 250 per minute when there is 1:1 atrioventricular conduction. Tachycardias with regular rhythm occurring in paroxysms lasting beyond a week are much more likely to be due to atrial flutter than to atrial paroxysmal tachycardia.

Sinus tachycardia differs from paroxysmal tachycardia in that it does not start or stop suddenly; the heart rate accelerates gradually, e.g., from 80 to 100, 120, 140 per minute and similarly subsides gradually instead of in a few beats as do the paroxysmal tachycardias. Furthermore, the cardiac rate in sinus tachycardia varies from minute to minute, especially with change in posture and exercise and occasionally with respiration. The heart rate in paroxysmal tachycardia persists with almost mathematical constancy (allowing a maximal variation of 2 beats per minute for difficulty in counting) despite posture, exercise or respiration. Atrial flutter may disclose equal constancy in cardiac rate, but occasionally there are sharp arithmetical divisions in rate due to heart block, e.g., the rate may be reduced to one-half its previous rate. With exercise, the ventricular rate in atrial flutter may increase in some arithmetical ratio, e.g., from 150 to 200 due to a change from 3:1 to 2:1 block, whereas the increase in rate following exercise is much more gradually progressive in cases of sinus tachycardia.

Carotid sinus pressure[171] may be of value in differential diagnosis as well as in treatment. *Sinus tachycardia* may not alter or it may respond with slight gradual slowing followed by a rapid return to the previous rate. *Atrial paroxysmal tachycardia* is usually suddenly reverted to normal sinus rhythm after a very brief pause or a few ventricular extrasystoles but often there is no effect. *Ventricular tachycardia* is not modified at all. *Atrial flutter* may be slightly and temporarily slowed or there may be a sharp reduction in rate due to increased atrial rate with induced heart block, but sinus rhythm is not restored as it is in atrial tachycardia. Slowing of the heart rate by carotid sinus pressure may also be useful when combined with electrocardiography using a lead from the third interspace to the right of the sternum. This slowing may reveal P waves previously obscured in T or QRS complexes and thus demonstrate atrial flutter with 2:1 block, independent atrial rhythm in paroxysmal ventricular tachycardia or an A-V nodal rhythm which was confused with atrial fibrillation or complete heart block.

Inspection of the cervical veins is more helpful in differential diagnosis.[180] Sinus tachycardia is associated with the normal "a," "c," "v" waves and the characteristic systolic collapse. In cases of atrial tachycardia the cervical veins may be prominent but not distinctive. On the other hand, ventricular tachycardia may be distinguished by the greater frequency of the heart rate as compared with the prominent jugular "a" pulsations (cannon "a" waves) due to retrograde A-V block. Atrial flutter may be diagnosed by the presence of characteristic rapid flutter "a" waves which are usually more frequent (2:1) than the heart rate.

The *heart sounds* may help to distinguish ventricular tachycardia, for there is sometimes a recurrent variation in the quality or intensity of the first sounds but not in atrial tachycardia. Furthermore, although the rate is persistently regular as in atrial tachycardia, the regularity may not be as mathematically constant in ventricular tachycardia. When listening for several minutes one may discover slight disturbances in the regularity of the heart beat. In atrial flutter, audible atrial contractions may be of differential diagnostic value. When bundle branch block accompanies supraventricular tachycardias, there is a wide splitting of the first sound.[180] In ventricular tachycardia wide splitting of the first and second sounds is the rule. If the heart sounds are single in the case of a rapid,

regular tachycardia, the diagnosis is supraventricular tachycardia

Irregular Tachycardias

If the tachycardia is irregular the arrhythmia is usually atrial fibrillation if the heart rate exceeds 130 per minute Below this rate the irregular rhythm may be due to numerous premature beats with sinus tachycardia Atrial flutter is occasionally irregular when there are dropped beats due to heart block or variations in the degree of block The rate may then be rapid or slow Paroxysmal atrial tachycardia due to digitalis toxicity may be irregular because of varying atrioventricular block Irregular tachycardia may be due occasionally to atrioventricular dissociation with interference or to ventricular tachycardia with interference Differentiation of the various irregular tachycardias is aided by artificial increase of the heart rate to 140 or more with exercise amyl nitrite or atropine This accentuates the irregularity if due to atrial fibrillation while that due to premature beats disappears The same procedure may be useful when there is uncertainty as to the presence of atrial fibrillation with normal or slow ventricular rates due to seeming regularity of the pulse It also differentiates this slow ventricular type of atrial fibrillation from cardiac irregularity due to sinus arrhythmia However exercise will not induce an irregularity when atrial fibrillation is associated with complete heart block and the ventricles are really beating regularly with their idioventricular rhythm or when the a v node becomes the pacemaker of the ventricles (a v dissociation) due to digitalis intoxication

Finally differentiation depends on and is made most certainly by a study of electrocardiograms the findings in which are discussed in detail under the individual headings Esophageal electrocardiograms and leads from the right side of the precordium are helpful when it is desirable to depict the P waves most clearly e g when conventional electrocardiograms fail to distinguish ventricular tachycardia from supraventricular tachycardia with bundle branch block

It is worthy of note that oppression of the chest or severe pain may so dominate the clinical picture of a paroxysmal tachycardia that it is mistaken for an acute myocardial infarction Occasionally this difficulty is enhanced by the association with the pain of weakness fall in blood pressure and pulse pressure and rarely of mild fever and leukocytosis However a careful history discloses that the onset was dominated by the tachycardia and palpitation and that the intense thoracic oppression or pain and the circulatory disturbances occurred secondarily Conversely paroxysmal tachycardias may develop after an acute coronary occlusion but they appear days after the basic clinical manifestations of acute myocardial infarction Sometimes the circulatory disturbances incidental to a severe and prolonged paroxysm of atrial tachycardia may induce myocardial infarction in patients with severe coronary atherosclerosis and deficient coronary reserve

From the diagnostic viewpoint it is appropriate to recall that the observation of paroxysmal atrial fibrillation should suggest a search for hyperthyroidism or less likely for mediastinal disease In cases of established atrial fibrillation without apparent cause one should consider the possibility of having overlooked an underlying mitral stenosis or masked hyperthyroidism

Chapter 15

DISTURBANCES IN CONDUCTION HEART BLOCK AND BUNDLE BRANCH BLOCK

The disturbances in conduction known as heart block may be classified as

1. Sinoatrial block
2. Atrioventricular block
3. Bundle branch block including intraventricular block
4. Short P R interval with prolonged QRS complex

SINOATRIAL BLOCK

Sinoatrial block is a disturbance in which the atrial response is delayed or omitted because of partial or complete interference with the propagation of impulses from the sinoatrial node to the atria [1,4] Experimentally such block has been produced and demonstrated by isolating the s a node through ligation and recording simultaneously the activity of the s a node and other parts of the atria [24] Despite regular sinus impulse formation there is no response of either atria or ventricles because the impulse cannot reach these structures In clinical experience such sinoatrial block cannot be distinguished from sinus arrest or sinoatrial standstill (p 325) in which there is a failure of sinus impulse formation

Electrocardiographically sinoatrial block is characterized by a pause during which a P wave and its accompanying QRST complex are lost (Fig 85) The P P interval is twice or almost twice the dominant P P interval Occasionally the block persists over two three or more cycles and the P P pause is correspondingly prolonged The pauses may not be exact multiples of a normal P P interval because as in all disturbances of the sinoatrial node there may be an associated sinus arrhythmia and because the sinoatrial conduction time may vary from beat to beat just as the a v conduction may vary in a v heart block

There may be recurrent sinoatrial block in which there is an interruption of alternate sinus impulses (2 1 sinoatrial block) The atrial rate becomes halved e g from 76 to 38 per minute and secondarily of course the ventricular rate is likewise halved This simulates sinus bradycardia electrocardiographically and atrioventricular heart block clinically If the sinoatrial block leads to a complete absence of atrial response the condition is termed atrial standstill (p 325) In this condition atrial contractions disappear for a long or short period while the ventricle responds to impulses from a lower center An analogy is sometimes made with atrioventricular block viz (1) isolated atrial pauses (partial sinoatrial block) corresponding to partial a v block with dropped beats (2) recurrent atrial pauses every second beat or third beat etc (high grade but incomplete 2 1 3 1 sinoatrial block) corresponding to incomplete 2 1 3 1 etc a v block and (3) atrial standstill with ventricular response to a v node or idioventricular center (complete sinoatrial block) corresponding to complete a v block with idioventricular rhythm Occasionally prolonged atrial standstill develops without the appearance of an a v nodal or other idioventricular pacemaker in consequence Adams Stokes attacks may occur because of prolonged ventricular standstill As a rule however after the dropping of a few beats an a v nodal beat escapes or with more complete sinoatrial block a v rhythm develops Electrocardiograms of sinoatrial block may have a bizarre appearance due to the intrusion of escape (a v nodal) beats and the appearance of unconducted normal atrial contractions (P waves without following QRS) due to their precocious development after the escape beat and while the ventricle is still refractory (See interference dissociation p 330)

There is a frequent association of a v block

with sinoatrial block. The former may be denoted by prolonged and varying P-R intervals or there may be complete heart block (p. 386). The sinoatrial block may appear occasionally in a case of permanent complete heart block,[a] or sinoatrial block may lead to almost complete atrioventricular dissociation without primary a-v block.[11]

Etiology

Sinoatrial block usually results from sensitivity to or intoxication by digitalis, quinidine, or Neo-synephrine or is associated with hyperkalemia. It may also be caused by vagal stimulation due to a sensitive carotid sinus, tumors compressing the carotid sinus, vagal reflexes during anesthesia and surgical procedures, or because of cerebral lesions. The reported occurrence of sinoatrial block with deep inspiration and its disappearance after the administration of atropine also support the causal importance of vagal influence.

According to Kisch and Zucker[15] sinoatrial block is never a physiologic phenomenon but is due to several factors acting together, e.g., myofibrosis in the region of the s-a node, increased vagal tone and coronary insufficiency. Sinoatrial block may be observed in the course of acute infections such as diphtheria, pertussis or mumps. *It is also possible that* sinoatrial block is due rarely to organic lesions in the neighborhood of the sinoatrial node, e.g., following atrial infarction.

Clinical Aspects

Sinoatrial block occurs much more rarely than atrioventricular block. It is usually of no clinical importance, but with long or frequent pauses in the heart beat the patient may experience dizziness, faintness or even attacks of the Adams-Stokes syndrome (p. 390). Death may occur when there is prolonged cardiac standstill.

Differential Diagnosis

Sinoatrial block may have to be distinguished from sinus bradycardia and from atrioventricular block. The electrocardiogram is usually distinctive. Clinically, atrioventricular block may be distinguished from sinoatrial block by the finding of atrial "a" waves in the cervical veins during the pauses in heart sounds in the former. Atrial "a" waves are absent in the pauses due to sinoatrial block.

Treatment

Treatment is rarely necessary since there are usually no symptoms. When sinoatrial block is due to digitalis or quinidine, these drugs should be stopped. If attacks of dizziness or syncope occur, atropine, 0.6 mg. to 1.0 mg. (1/100 to 1/60 grain), may be given subcutaneously and repeated after two to four hours as needed and tolerated. Ephedrine, 25 mg. (3/8 grain), every four to eight hours as tolerated, may also be useful. For attacks of syncope or Adams-Stokes syndrome, epinephrine may be given parenterally (0.3 to 1.0 cc. of 1:1000 solution) or isopropyl arterenol (Isuprel) 5 to 15 mg. may be administered sublingually at regular intervals as required to prevent the attacks (p. 393).

Fig. 85. Sinoatrial block in woman aged 57 with diabetes and coronary artery disease. Pauses approximately equal to two normal intervals in long strips. After the first pause there is a nodal beat.

ATRIOVENTRICULAR BLOCK

Atrioventricular block is the cardiac mechanism resulting from defective conduction of the impulse from atrium to ventricle. There may be merely a delay in transmission of the impulse through the a-v node and bundle, or there may be a complete interruption of occasional or of all impulses. Accordingly, atrioventricular block is classified as:

1. Prolonged atrioventricular conduction time (first degree block)
2. Partial heart block (second degree block)
3. Complete heart block (third degree block)

Heart block may be transient or permanent and it may represent a functional or organic disturbance. Complete heart block may appear in recurrent attacks with normal conduction between attacks.[17] Heart block is one of the commoner disorders of the heart beat. Its incidence is uncertain because the lesser degrees of heart block are mostly overlooked

However it is probable that heart block is exceeded in frequency only by premature beats atrial fibrillation and paroxysmal atrial tachycardia Prolonged a v conduction time partial heart block and complete heart block are encountered in that order of frequency

Mechanism

Experimentally atrioventricular block can be produced by cutting ligating clamping or otherwise injuring the a v bundle (of His) [3] Ligation or artificial embolization of the coronary arteries the application of destructive chemicals or cold drugs such as morphine epinephrine or digitalis diphtheria toxin asphyxia [28] and vagal stimulation (especially of the left vagus[29]) have been employed to cause heart block experimentally The toxic agents produce heart block either by direct action on the conduction tissue or indirectly through vagal stimulation or both It has been shown that the most susceptible site i e the site responsible for the block is the upper portion of the atrioventricular node

If the bundle is only partially divided with varying degrees of completeness or if progressive degrees of compression are applied various stages of heart block are induced (1) The sinoatrial impulses may all traverse the a v node and bundle and cause a ventricular response but the delay in conductivity results in a prolonged atrioventricular (or P R) interval (2) Occasional sinus impulses cause atrial contractions but are not followed by a ventricular response (3) There is a regular sequence of dropped beats with an atrioventricular ratio of 8 7 5 4 or 4 3 etc Or the ventricle responds to every second third or fourth atrial contraction resulting in 2 1 3 1 or 4 1 block (4) Finally with complete block none of the atrial impulses reaches the ventricles However the ventricles continue to beat independently of the atria (a v dissociation) in response to a pacemaker in the a v bundle below the site of block or rarely in response to a pacemaker in the ventricular musculature (idioventricular rhythm) If at the onset of complete heart block a new pacemaker fails to appear ventricular standstill occurs

The Electrocardiogram

1 *Prolonged Atrioventricular Conduction Time* The P R interval exceeds 0 2 second (Fig 86) It may be as long as 0 3 second and occasionally 0 5 second or more As a rule every P wave is followed by a QRST complex and the waves are normal in configuration In such instances the rhythm of the heart is regular and the prolongation of a v conduction is betrayed only by the electrocardiogram However delayed atrioventricular conduction may be combined with more severe degrees of a v block When the P R interval exceeds 0 3 second there are usually occasional dropped beats which result in some irregularity

Normally the P R interval varies between 0 12 and 0 2 second At slow cardiac rates (60 per minute or less) a P R interval up to 0 21 or 0 22 may be normal P R intervals exceeding 0 2 second and up to 0 28 second were found in 16 of 1000 young apparently healthy aviators [30] A follow up study after ten years showed that none of the individuals with a prolonged P R interval had developed clinical evidence of heart disease [31] When the prolonged P R interval is due entirely to widening of the P wave there is no impaired conduction through the a v node and bundle With very long P R intervals or with rapid rates the P R interval may be difficult to measure because the P wave becomes obscured by the preceding T or QRS complex The presence of a very high or deformed T wave often suggests fusion with the following P wave

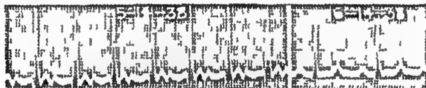

Fig 86 Atrioventricular block in rheumatic fever Lead II May 14 P R interval prolonged to 0 28 during rheumatic activity June 14 ventricular rate slowed but P R interval still prolonged

2 *Partial Heart Block (Second Degree Block)* There are various grades of partial heart block according to the frequency with which atrial impulses are not followed by ventricular contractions

(a) Periodically there is a dropped beat For example, there may be seven P waves followed regularly by QRST complexes while the eighth P wave has no subsequent ventricular complex If the ninth P wave and corresponding ventricular complex follow at their regular interval the mechanism would be termed an 8 7 block denoting 7 ventricular responses to 8 atrial beats The contours of the various waves are unaltered

(b) Occasionally the P-R interval increases progressively until a QRS complex falls out Following this the P R interval becomes smaller but thereafter again increases progressively until there is another dropped beat and seriatim This has been termed the Wenckebach phenomenon and the increasing intervals between beats are called Wenckebach periods (Fig 87) It is believed that the

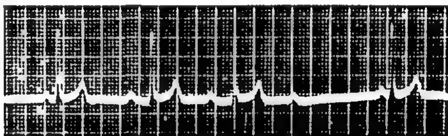

Fig 87 Atrioventricular block with Wenckebach periods Lead II Progressive prolongation of P R interval until after fourth P wave a beat is blocked P R interval after pause is shortened.

Fig 88 Incomplete heart block 3 1 Lead II There is a ventricular response to every third sinus impulse and the P R interval is constant

progressive delay in conduction denotes increasing fatigue of the a v node or bundle until it is incapable of conducting an impulse at all With the rest period occasioned by the dropped beat, the bundle recovers partially, the P R interval is somewhat shorter but again with each conducted impulse the speed of conduction becomes impaired In this type of partial heart block the ventricular rhythm is irregular, partly because of the changing P R interval and partly because of the dropped beats

(c) With more severe partial heart block the ventricles respond only to every second, third or fourth beat resulting in 2 1, 3 1 or 4 1 block (Fig 88) This is indicated by QRST complexes following every second, third or fourth P wave, but not the intermediate P waves The ventricular rate is usually regular and may be slow if the atrial rate is normal However, the ventricular rate may be rapid e g , 150 per minute in cases of atrial flutter with atrial rates of 300 per minute and a 2 1 heart block At times there is a dominant degree of block e g 3 1 with variations from 2 1 to 4 1[29] In such cases there may be an irregularity in the ventricular rate *High grade block* denotes almost complete heart block with only occasional sinus impulses eliciting a ventricular response (Fig 89)

3 **Complete Heart Block** The essential electrocardiographic feature of complete heart block is the virtual regularity of atrial and ventricular activity with continual variation in the P R interval (Fig 90) The atrial rate is higher than the ventricular rate, i e , there are more P waves than QRS complexes But both the atrial and the ventricular rhythms are essentially regular As a rule the atrial rate is 70 to 80 per minute (normal), while the ventricular rate is 30 to 40 or half as great This simulates but should not be confused with 2 1 block, for in 2 1 partial heart block the QRS complexes follow every second P wave after a constant interval There may be not only complete atrioventricular block but also a 2 1 idioventricular block, i e , the idioventricular impulse may be blocked and the ventricular rate may be less than 15 per minute (double a v block)[14]

The QRS complexes bear no constant time

relationship to the P waves Measurement of the P R intervals discloses irregular variations The QRST complex represents a response to a pacemaker in the a v junctional tissue or in the ventricles while the P wave denotes excitation by the sinoatrial node There is, therefore an atrioventricular dissociation in complete heart block The occurrence of interference with dissociation has been described (p 330) Occasionally P waves recur regularly while there is an abnormally long period without QRS complexes (ventricular asystole) (Fig 91)

block Occasionally complete heart block results from bilateral bundle branch block (p 395) The electrocardiogram is then characterized by atrioventricular dissociation with bizarre QRS complexes like those of ventricular premature beats or bundle branch block (p 335) A distinctive feature in these cases is the tendency for the QRS complex to shift in configuration from the right to the left or from the left to the right type of ventricular premature beat or bundle branch block[44] Ide[44] noted the QRS complexes of left bundle branch block in 18 and of right

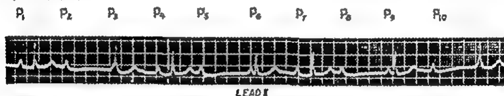

Fig 89 Heart block of very high grade with irregular ventricular rhythm Atrial rate 78 per minute Atrial rhythm almost regular but the P P intervals including the QRS-T are slightly shorter (0 70 sec) than the others (0 84 sec) P_1 P_4 and P_7 elicit a ventricular response Other QRS complexes represent independent (escaped) nodal rhythm

Fig 90 Complete atrioventricular heart block during acute myocardial infarction Ventricular rate 35 Atrial rate 130 Constantly changing relationship between P and R

Fig 91 Complete atrioventricular block with prolonged ventricular asystole

The QRS complexes in complete heart block[44] *are usually of normal configuration* although slight distinctive modifications are observed intermittently when a simultaneous P wave is incorporated in the QRS The normal supraventricular configuration of the QRS complex denotes that the governing impulse arises in a center within the bundle of His or a v node below the site of obstruction and that its subsequent course through the bundle branches and ventricular musculature is normal If however the pacemaker for the ventricles arises in an ectopic focus in the ventricular musculature or in one of the bundle branches the QRS complexes appear widened slurred or notched (aberrant QRS) But similar aberrant complexes may be due to bundle branch block associated with atrioventricular

bundle branch block in 8 instances in a total of *71 cases of complete heart block In 11 of* these the bundle branch block was noted at times when the complete heart block was absent

Although the P waves in cases of complete heart block are usually normal in configuration rate and rhythm they may be absent or replaced by 'f' waves when atrial fibrillation is associated In Ide's series of 71 cases of complete heart block atrial fibrillation was associated in 20 Atrial flutter may also be associated with complete heart block[44] [n] The rate of the P waves may also be accelerated if heart block is combined with atrial flutter or tachycardia

The P waves may not recur with absolute regularity for both in partial [illegible] and com-

plete heart block the P P periods in which a QRS complex falls may be slightly briefer than the other P-P intervals This indicates that the atrial impulse may in some way be influenced by a preceding ventricular contraction,[98] perhaps through modification of vagal tone [illegible] Sometimes more severe types of irregular sinus rhythm occur in heart block the mechanism for which has been variously explained [illegible] [11] The P waves following a QRS may appear to be premature but are usually distinguishable from an atrial extrasystole because in the latter the configuration of the P wave is altered as well as premature Occasionally this distinction fails because the shape of a P wave in cases of heart block may be abnormal if it occurs early in diastole

Sometimes there is retrograde conduction from the ventricular pacemaker to the atrium despite the complete heart block This depends on the time relationship of the idioventricular beat to the preceding normal atrial contraction In order to produce an atrial response the ventricular impulse must arrive when the atrial musculature is no longer refractory

Following stimulation of nerve or muscle there is a period of *complete refractoriness* to further stimulation followed by a *relatively refractory* period when these tissues respond only to stronger stimuli than are usually effective Under certain circumstances, during the recovery period following stimulation there is a brief stage when the muscle may respond to weaker stimuli than usual (i e subthreshold stimuli) This is known as a *supernormal recovery phase* and is observed occasionally in cases of heart block, early in diastole [illegible] Thus P waves occurring early in diastole may be conducted while those occurring late in diastole are blocked The supernormal phase of conduction has also been related to the occurrence of premature beats at this stage of the cardiac cycle

Etiology and Pathology

The commonest clinical causes of heart block (including all degrees of severity) are

1 Chronic forms of heart disease especially severe coronary heart disease, calcific aortic stenosis (usually rheumatic) and less often other forms of rheumatic heart disease, congenital heart disease syphilitic heart disease, syphilitic gumma and gummatous myocarditis, and neoplasms

2 Digitalis in full doses and, less commonly quinidine

3 Acute infectious diseases, notably rheumatic fever and diphtheria but at times almost every other infection

4 The tachycardias Atrial extrasystoles

In Ide s[39] series of 71 cases of complete heart block coronary and hypertensive heart disease was present in 41, digitalis intoxication in 12, and in 9 others the heart block was regarded as congenital As a rule the causative factors under the last three headings induce only a functional and transient heart block,[40] while the chronic forms of heart disease, being associated with anatomic lesions, give rise to heart block which is usually but not always permanent In many instances in which *functional disturbances* are responsible for precipitating heart block there is also organic heart disease which acts as a predisposing or contributory factor

Various forms of *reflex vagal stimulation* may account for transient heart block, characterized usually by a prolonged atrioventricular conduction time but occasionally by complete a v dissociation Heart block may result from compression of the carotid sinus or pressure over the eyeball through the intermediation of vagal reflexes Mackenzie[70] had already noted that swallowing which reflexly stimulates the vagus produced a failure of ventricular response in a patient who previously exhibited only a prolonged atrioventricular interval Similarly Weiss and Ferris[1 8] described the occurrence of Adams Stokes attacks with transient complete heart block due to a vagovagal reflex provoked by a traction diverticulum of the esophagus In at least two of the cases of heart block reported by Holmes and Weill [33] in which heart block was present when the subjects were in the supine position and abolished by standing vagal influence was demonstrated

The heart block caused by *digitalis* may likewise be due to the vagal action of the drug for it is sometimes abolished by full doses of atropine However, the heart block is more often caused by a direct inhibitory effect of the digitalis on the a v node and bundle [19] While digitalis may induce heart block of all degrees even in normal subjects the effect is more readily produced when there is already an underlying conduction disturbance The a v block associated with sinoatrial block and a v rhythm has been noted (pp 383, 328)

usually these combinations result from digitalis or vagal stimulation or both

In *rheumatic fever* prolongation of the P R interval occurs commonly and is a valuable diagnostic finding, severer grades of heart block also occur Heart block often of advanced degree is an important and serious complication of *diphtheria* as it denotes a severe diphtheritic myocarditis (p 907) Usually these cases end fatally However Leys[85] reported complete a v dissociation in a woman of 25 years which he believed was caused by an attack of diphtheria at the age of 10 Since heart block is also observed in a vast number of other infections such as pneumonia scarlet fever grippe mumps German measles in which lesions of the conduction system have not been demonstrated and are improbable the heart block may be due in part to a toxic effect on the a v node and bundle Such a toxic influence may also contribute to the heart block of rheumatic fever and diphtheria independently of any local lesions The occurrence of heart block during convalescence from many infectious diseases suggests that vagal influences may be significant

In most instances of heart block associated with acute infections there is only a prolongation of the P R interval In such cases the P R interval may often be shortened to normal by the administration of atropine This suggests a vagal factor in the production of the heart block Even in cases of prolonged P R interval due to organic causes such as coronary atherosclerosis or calcific aortic stenosis atropine may normalize the P R interval

The heart block accompanying many paroxysmal tachycardias such as atrial flutter and fibrillation and occasionally atrial paroxysmal tachycardia is generally believed to result from a functional fatigue and refractoriness of the a v node and bundle consequent to the great frequency of atrial impulses trying to gain admission to the ventricles

Coronary Atherosclerosis is the chief cause of permanent heart block which may be partial or complete However transient heart block also occurs following an acute coronary occlusion Heart block when present is almost always the consequence of an occlusion of the right coronary artery since a branch of this vessel supplies the a v node and bundle in more than 90 per cent of hearts Massive infarction of the septum is apt to be associated with heart block because an extensive septal infarction usually denotes occlusion of both left and right conorary branches

That coronary artery occlusion (or severe narrowing) does not more frequently produce atrioventricular block is explained by two circumstances (1) Left coronary artery occlusion rarely produces heart block because the conduction tissues almost always receive their blood supply from the right coronary (2) Right coronary artery occlusion uncommonly produces heart block because the septal branch to the a v node and bundle comes off very early and the occlusion is usually distal to the origin of this branch As a rule histologic examination discloses necrosis degenerative changes or fibrosis of the a v bundle or of both bundle branches[147] However a v block may result from tissue anoxia due to a deficient blood supply to the a v node and bundle[94]

In instances of *calcific aortic stenosis* which is almost always rheumatic in etiology various degrees of heart block may result from extension of the calcific process from the aortic ring to the junctional conduction tissue in the septum However conduction disturbances in this disease may be due also to anoxia of the bundle caused by functional coronary insufficiency (p 701) Calcific aortic stenosis may resemble coronary arteriosclerosis with respect both to conduction disturbance and to the presence of angina pectoris because of relative deficiency of the coronary circulation Heart block may be due to deposits of calcium in the bundle in association with calcification of the annulus of the mitral valve with or without concomitant calcification of the aortic valve[115]

Syphilis is an uncommon cause of organic and usually permanent heart block The conduction disturbance may be due to a gumma infiltrating the bundle of His or both bundle branches to a gummatous myocarditis extending from the aorta or to coronary insufficiency caused by syphilitic aortitis with narrowing of the coronary ostia

Congenital heart block occurs uncommonly but there are several reports of cases[113, 19, 104, 150] It probably composes 10 to 15 per cent of all cases of complete heart block and one-half of those occurring below the age of fifty[19] It results from a defect in the course or development of the junctional conduction tissues and

may be associated with interventricular septal defects.[10a] Congenital heart block without evidence of a septal defect was found in two siblings, in one of whose parents there was also a Wolff-Parkinson-White syndrome.[131] Detailed histologic studies reported by Yater, Leaman and Cornell[148] disclosed a separation of the a-v node from the bundle of His by the central fibrous body. Other occasional or rare causes of heart block, usually permanent and associated with anatomic lesions, are bacterial endocarditis with extension of the bacterial inflammatory changes to the septum, neoplasms, tuberculosis and cysts invading the conducting tissues and traumatic lesions. Heart block has also been noted with aneurysm of the sinus of Valsalva of congenital or bacterial origin.

Age and Sex. In a study of 64 cases of severe heart block, mostly complete, Campbell[10] found that 46 were in the age range between 50 and 70 and that males predominated in the ratio of 4:1. In Ide's series[22] the peak incidence occurred between 70 and 80 years of age and males predominated in a ratio between 2 and 3:1.

Clinical Features

Subjective symptoms are generally absent since the rhythm is usually regular and the rate is either normal or slow. Bradycardia is much better tolerated than tachycardia as regards both precordial discomfort and circulatory disturbances. When impaired conduction is limited to prolonged conduction time, there are never any symptoms. In fact, heart block is usually discovered accidentally during routine examinations, and first degree heart block (prolonged P-R interval) is a chance discovery in electrocardiographic examinations. On occasion there may be local symptoms consisting of precordial discomfort or palpitation due to relatively long pauses between beats or to the thumping of the strong ventricular contractions following the pause. There may be recurrent sensations "as if the heart stops," accompanied by intense anxiety and other psychogenic symptoms. Weakness, precordial or epigastric pain occurs occasionally.

In most instances of heart block there is no significant circulatory disturbance. The dynamics of the heart in complete heart block has been elucidated by studies with rapid biplane angiocardiography with simultaneous electrocardiography.[illegible] Sometimes in the presence of heart block, with slow ventricular rate, the heart may be compensated at rest but not under the stress of exercise. With partial heart block of lesser severity, the heart rate increases with exercise and excitement. On the other hand, the degree of block may be enhanced by exercise and the ventricular rate may be slowed instead of accelerated. When block is complete, the circulation may become insufficient during exercise because of the failure of the ventricle to compensate by an increased rate. An effective circulation is usually maintained even when the ventricular rate is as slow as 20 to 30 per minute. The deficiency in cardiac rate is compensated by the prolonged diastolic period available for ventricular filling and myocardial recovery; this results in an augmented stroke output. But when the pause between beats is sufficiently long (more than 3 to 5 seconds), the patient may experience dizziness or vertigo, faintness or attacks of syncope. These symptoms are observed, as a rule, in the severer grades of partial heart block or in cases of complete heart block, and in older individuals in whom cerebral atherosclerosis may be a predisposing or contributory factor. A history of syncope or convulsions is not uncommon in the cases of congenital heart block.

Morgagni-Adams-Stokes Syndrome **(Adams-Stokes, Stokes-Adams).** This refers to attacks of syncope with or without convulsive seizures due to prolonged asystole (five to ten seconds or more) (Fig. 91). The patient becomes pale, loses consciousness and is found to be pulseless. In more severe attacks (fifteen seconds or more) the pallor is combined with or replaced by cyanosis, the breathing becomes deep and stertorous and a generalized convulsion develops. There may be an associated *Cheyne-Stokes respiration.*[35] After twenty seconds or longer the twitchings disappear, the pulse returns, normal color is restored and the breathing becomes quiet. Nonfatal paroxysms rarely exceed sixty seconds in duration, but recovery has followed longer periods of asystole lasting five to twenty minutes.

These attacks usually occur when there is a failure of ventricular contraction in the course of complete heart block, or when there is a delay in the establishment of idioventricular rhythm in the transition from normal sinus rhythm to partial or complete heart block,[illegible] or in shifts between incomplete and complete

heart block There may be simultaneous atrial and ventricular standstill[173] Adams Stokes syndrome due to paroxysmal ventricular standstill which could be reproduced by carotid sinus pressure was reported in a patient with right bundle branch block but without heart block between the paroxysms[21] Either nervous influences or progressive coronary insufficiency may explain why the regularly contracting ventricle in complete heart block suddenly stops for more or less prolonged intervals Similar Adams-Stokes seizures occur when asystole is the result of periods of ventricular tachycardia or fibrillation with or without associated complete heart block[109] (p 377) Syncope from cardiac standstill may also occur in the normal heart as a result of vagal reflexes from a sensitive or compressed carotid sinus or in instances or sinoatrial block

Other symptoms and signs observed in cases of heart block are those of the associated causative condition or underlying heart disease Manifestations of angina pectoris or of congestive heart failure are not uncommon

Signs of Heart Block There are no physical signs of prolonged atrioventricular conduction time However when sufficiently prolonged it may tend to produce a gallop rhythm and the first heart sound may be diminished in intensity The gallop rhythm results from segregation of the atrial sound by the long P R interval

With prolonged atrioventricular conduction and occasional dropped beats the heart rhythm is regular while the blocked impulses are denoted by pauses

With severe degrees of partial heart block 2 1 3 1 etc or with complete heart block the cardiac rate is slow (40 per minute or less usually but 50 per minute is common in complete heart block that is congenital rheumatic or due to digitalis) In cases of diphtheritic heart block there is often a terminal ventricular tachycardia and there may be a high idioventricular rate of 80 to 100 The rhythm may appear regular or in partial heart block there may be abrupt transitions in cycle lengths In complete heart block the changing time relationship between atrial and ventricular contraction and the consequent change in position of the a v cusps results in corresponding variations in the intensity of the first heart sound[112] The atrial sound may be heard faintly between the regular heart sounds, or by coincidence or close proximity with them cause accentuation or reduplication of the first or second sound In instances of mitral stenosis associated with complete or 2 1 heart block a murmur may be audible with each atrial beat which falls during ventricular diastole

Not infrequently calcification in the interventricular septum can be demonstrated radiologically in cases of heart block[137] There are also often signs of associated heart disease including those of cardiac enlargement and electrocardiographic evidence of previous myocardial infarction

Diagnosis

The diagnosis of delayed atrioventricular conduction can only be made by the electrocardiographic finding of a prolonged P R interval (or by analysis of jugular venous tracings) Its presence may be suspected from the development of a gallop rhythm or variations in intensity of the first heart sound during or after infectious diseases especially rheumatic fever

When the delayed conduction is associated with dropped beats partial heart block is suspected from the regular rhythm with intermittent pauses This may have to be distinguished from premature beats in which however the pause follows a fast (precocious) beat Sometimes auscultation fails in this differentiation as the weak sound of the atrial beat may be indistinguishable from the weak sound of a premature beat Partial heart block is diagnosed essentially by electrocardiographic examination (p 385)

Severe partial heart block e g 3 2 2 1 or 3 1 block or complete heart block should be considered with slow apical and pulse rates of 25 to 50 per minute Occasionally rates below 15 per minute have been recorded[14] However congenital complete heart block is often overlooked because the ventricular rate is relatively fast 40 to 56 and in diphtheritic heart block it may exceed 80 Congenital heart block has been diagnosed in utero by the fetal electrocardiogram and sound tracings with simultaneous electrocardiogram of the mother[4] The diagnosis was suggested by the slow fetal heart rate Severe partial and complete heart block must be distinguished from each other and from intense sinoatrial bradycardia and from sinoatrial block Atrioventricular block may be distinguished from the others by the findings of more atrial (a)

waves in the jugular veins than apical beats. The atrial waves may be observed during the ventricular pauses determined by simultaneous auscultation of the heart. Attempts to increase the heart rate by exercise, atropine or amyl nitrite may be helpful in that the rate increases most in sinus bradycardia and not at all or very slightly in complete heart block. In partial heart block there may be a slight increase in heart rate or an abrupt slowing due to further impairment in a-v conduction. Carotid sinus pressure may further slow the heart rate when the block is partial or have no effect in the presence of complete heart block. Complete heart block may also be distinguishable from partial heart block by the irregular change in intensity of the first heart sound in the former. From time to time there is a sharp accentuation of the first sound at the apex ("cannon sounds").

The diagnosis of severe heart block may be suspected from the occurrence of Adams-Stokes seizures. Usually a-v block is discoverable in electrocardiograms taken between attacks but rarely heart block occurs only during the attack. Among the diagnostic features confirming the suspicion that the attack is due to heart block are: absence of heart or pulse beat during the attack while the atrial sounds may be heard on auscultation and the atrial "a" waves may be seen in the cervical veins; the relatively longer duration of the attack in heart block than in vagal cardiac standstill. The finding of a very slow pulse after recovery also suggests that the syncope was due to heart block. However the heart rate may be 90 or higher as the patient is recovering especially if he is under the influence of drugs, after several hours the pulse slows again. For electrocardiographic diagnosis of complete heart block, see page 386.

Prognosis

The clinical significance and the prognosis of heart block depend on the causative factor. The average duration of life following discovery of complete heart block was [illegible] 5 years among 34 patients reported by Campbell.[10] But a number of instances of longevity with complete atrioventricular block have been reported.[6, 108] Heart block due to vagal reflexes, to digitalis toxicity or to extreme tachycardia is usually insignificant in itself and transient in duration. The underlying conditions responsible for the vagal reflex, the tachycardia or for the administration of digitalis may however, be serious. They, not the heart block, determine the prognosis.

Similarly, various grades of heart block occurring with infectious diseases are usually self limited in duration (hours, days or a few weeks) and scarcely modify the outlook of the basic disease itself. However the heart block occurring with rheumatic fever, and less often with other infections, may persist although this is exceptional. In diphtheria heart block is often of ominous significance but only because it occurs in intensely toxic cases in which there is a severe myocarditis. However if recovery ensues there is no evidence of chronic diphtheritic heart disease. In general it may be stated that the seriousness attached to heart block is justified only when it is a manifestation of a serious underlying disease or toxic state. Sometimes the observation of heart block first suggests the search for and the discovery of some underlying disease or digitalis intoxication.

Heart block is often associated with heart disease and in such cases the outlook varies according to the type of heart disease and its severity. Congenital heart block in subjects surviving childhood is usually compatible with normal activities (including pregnancy, childbirth and manual work) and with a normal life span.[10, 108] Heart block may be transient during an attack of acute coronary occlusion but often it persists and becomes progressively more complete. Heart block in syphilitic heart disease may diminish following antisyphilitic therapy, possibly due to resorption of a gumma.

The development of the Adams-Stokes syndrome with heart block is often of serious omen. Cases of heart block associated with bundle branch block are said to be associated more frequently with Adams-Stokes syndrome and an unfavorable prognosis than those associated with the normal supraventricular type of QRS complex.[illegible] An attack may occur at the onset of heart block but may never again appear. On the other hand these attacks may appear infrequently at first but shortly occur more and more often and with increasing severity. They often denote severe myocardial disease. Death may occur during one of the attacks due to prolonged ventricular standstill. As a rule death occurs suddenly in patients with heart block and Adams-Stokes syndrome. In other cases of complete heart

block associated with coronary and hypertensive heart disease but without Adams Stokes attacks heart failure is the common cause of death

Treatment of Heart Block and the Adams Stokes Syndrome

Treatment is rarely indicated for the heart block itself as it usually is not responsible for symptoms and clears spontaneously Treatment of the causative factor may result in abolition of the heart block Digitalis quinidine and opiates should be stopped If these are responsible for the heart block it will disappear rapidly If their use is essential the heart block may not recur with smaller doses

Heart block may require more specific treatment when it is associated with symptoms especially dizziness faintness or Adams Stokes seizures Treatment may be necessary for the acute attack or to prevent recurrent attacks Direct thumping of the precordium may restore the heart beat when there is prolonged ventricular standstill As a rule drugs must be employed to control the attacks of Adams Stokes syndrome

Epinephrine hydrochloride and *isopropyl norepinephrine* (Isuprel) are the drugs of choice Epinephrine may be injected subcutaneously or intramuscularly in doses of 0 3 to 1 0 cc (5 to 15 minims) but only when the Adams-Stokes syndrome is due to ventricular standstill When the attacks recur with great frequency e g during an acute attack of myocardial infarction this dose may have to be repeated every two hours for a day or two After the first injection or two epinephrine in oil (1 cc contains 2 mg of epinephrine) may be given intramuscularly for prolonged effect This may be repeated after 12 to 24 hours if necessary However this form of therapy has usually appeared to be less effective than more frequent injections of the aqueous epinephrine The intervals can be prolonged and the drug finally discontinued if the attacks regress or subside With dangerously prolonged ventricular standstill an intracardiac injection of epinephrine may be lifesaving but there is some risk that epinephrine will induce ventricular fibrillation It is important to obtain electrocardiographic tracings to be certain that asystole is due to ventricular standstill and not to ventricular tachycardia fibrillation Epinephrine is useful in the former condition because it increases ventricular irritability On the other hand because of this action it is contraindicated in ventricular fibrillation which it tends to prolong rather than alleviate

Isopropylnorepinephrine (*Isuprel*) represents an important advance in the management of the Adams Stokes syndrome Like epinephrine Isuprel increases the cardiac rate the stroke volume the amplitude of myocardial contraction and the coronary blood flow There is a slight rise in systolic and a similar fall in diastolic blood pressure [74] Isuprel increases myocardial irritability more than epinephrine or other sympathomimetic drugs but whereas epinephrine stimulates both the higher and lower cardiac centers Isuprel acts predominantly on the higher centers (sinus and atrioventricular node) [149] It tends to increase the rate of the pacemaker in atrioventricular block usually relocating the pacemaker in the vicinity of the atrioventricular node [107]

Isuprel shows the least tendency to produce cardiac automaticity i e to induce ventricular fibrillation Aside from this superiority over epinephrine it also possesses the advantages of not causing the tremor blanching of the skin and other nervous symptoms produced by epinephrine and of effectiveness when administered sublingually It may also be administered subcutaneously or intravenously Isuprel has been effective in cases of Adams-Stokes syndrome associated with ventricular tachycardia[107] and ventricular fibrillation [91] as well as those with ventricular standstill

Isuprel available in 5 and 10 mg sublingual tablets may be administered sublingually in doses of 10 to 20 mg or subcutaneously 0 2 mg every one to six hours or as required to prevent attacks Isuprel has been administered as a continuous intravenous infusion containing 1 mg of the drug in 200 cc of 5 per cent glucose in distilled water (5 micrograms per cubic centimeter) with the rate of flow adjusted to 9 to 20 drops per minute [■]

Sodium Lactate The intravenous administration of sodium lactate has been reported to control the Adams-Stokes syndrome due to ventricular asystole as well as episodes of cardiac arrest the slow idioventricular rhythm of complete atrioventricular heart block and the slow ventricular rate of partial atrioventricular block and sinus bradycardia [6] The dose employed ranged from 15 cc of molar sodium lactate administered intravenously in

one minute to 960 cc (molar and half molar solution) in five hours according to the urgency of the situation and the response Calcium gluconate may have to be given to prevent or control tetany due to the induced alkalosis Although the mechanism of action of the sodium lactate is uncertain it was thought to increase cardiac rhythmicity chiefly as a result of alkalosis

Methamphetamine (Desoxyn) Syncopal attacks were controlled in 2 cases of Adams Stokes syndrome following acute myocardial infarction by the repeated injection of 20 to 40 mg of Desoxyn subcutaneously, intramuscularly or intravenously A sterile solution of the drug is available in 1 cc ampules containing 20 mg [15]

Oxygen and *aminophylline* (administered intravenously or by rectal suppository) may be useful adjuncts in the treatment of Adams-Stokes syndrome

Atropine sulfate 1 to 2 mg (1/60 to 1/30 grain) may be administered when heart block is due to vagal influences It is sometimes given in conjunction with epinephrine in attacks of Adams-Stokes syndrome

For more chronic use or to alleviate attacks of moderate frequency in ambulant persons other sympathomimetic drugs may be given orally ephedrine 15 to 30 mg (¼ to ½ grain) three to five times daily, Paredrine, 20 to 60 mg (⅓ to 1 grain) three to five times daily If palpitation or nervous symptoms develop, these drugs should be combined with sedatives None of these has proved as effective or useful as epinephrine or Isuprel Atropine may be combined with ephedrine or Paredrine

Barium chloride has been used in doses of 20 to 60 mg (⅓ to 1 grain) because of its tendency to increase ventricular irritability, but its efficiency is questionable

Digitalis would seem to be contraindicated because of its vagal stimulating effect and its tendency to impair a v conduction by direct action on the a v node and bundle Nevertheless it has on occasion prevented attacks relieved symptoms due to heart block or eliminated the heart block itself when all other measures failed The explanation for this effect of digitalis is uncertain but it may be related to its improvement of myocardial efficiency Of course when there are definite signs of congestive heart failure digitalis should be administered as usual, regardless of the heart block

Thyroid extract and thyroxin have been recommended both for acute attacks of ventricular asystole and to prevent recurring attacks Its value for this purpose is unproven Recurrent attacks of syncope associated with ventricular asystole due to a hypersensitive carotid sinus were abolished by inducing mild hyperthyroidism with large doses of thyroid hormone [88] Corticotropin administration eliminated attacks of syncope associated with cardiac arrest in a case of myocardial infarction presumably by suppressing inflammation and abolishing heart block [33]

Quinidine is contraindicated because of its depressant effect in the junctional tissues It was hoped that quinidine would be effective in cases of Adams-Stokes syndrome due to ventricular tachycardia and fibrillation But it was noted that in patients with complete heart block quinidine tended to produce ventricular tachycardia, other prefibrillatory mechanisms and ventricular fibrillation [109, 14]

Procaine amide (Pronestyl) is likewise contraindicated in the treatment of Stokes-Adams syndrome associated with heart block whether the Adams-Stokes syndrome is due to ventricular standstill or ventricular fibrillation [108] The administration of procaine amide in patients with heart block has been followed by further reduction in the ventricular rate by multifocal ventricular extrasystoles and by paroxysms of ventricular tachycardia or ventricular fibrillation Neither has it been effective in preventing or eliminating runs of ventricular fibrillation associated with heart block [77]

Artificial Cardiac Pacemaker for Ventricular Standstill and Adams Stokes Syndrome Resuscitation from Adams Stokes attacks due to ventricular asystole or a very slow idioventricular rate may be effected by the application of external electric stimulation with an artificial portable cardiac pacemaker [150, 95] This is a modification of existing physiologic stimulators and produces monophasic rounded electrical impulses with an average duration of 2 to 3 milliseconds and with the entire wave form lying above the baseline The pacemaker is attached to the patient by two output wires connected to circular chest electrodes, 3 cm in diameter The negative electrode is usually placed at the point of maximum cardiac impulse the positive electrode symmetrically on the right anterior chest or on the left posterior chest Electrical contact is facilitated by the application of electrode paste

and the electrodes are maintained in place by a rubber strap encircling the chest

The patient is grounded by the negative output wire from the pacemaker Usually the patient is also connected to an electrocardiograph and the patient the artificial pacemaker and the electrocardiograph must have a common ground by wires between the electrocardiograph and the pacemaker and between the pacemaker and an external ground The frequency of stimulation is set between 60 and 90 per minute and the amplitude control increased from zero until cardiac responses are obtained Thereafter effective cardiac stimulation is maintained by amplitudes slightly above the threshold level In the experience of Zoll et al [150] the current with effective stimuli ranged from 75 to 150 milliamperes and the voltage from 45 to 100 volts Rosenbaum and Hansen[93] developed an inexpensive portable cardiac stimulator combining a defibrillator and pacemaker This offers promise of both defibrillation and restoration of cardiac contraction without thoracotomy See also Zoll et al [151] (p 1109)

By means of the artificial pacemaker Zoll et al [150] resuscitated 11 patients from attacks of Adams-Stokes syndrome due to ventricular standstill maintained an adequate circulation during persistent ventricular standstill and prevented the recurrence of irregular ventricular tachycardia Three patients survived for many months following resuscitation from recurrent syncope This suggested that the factors responsible for the syncope may subside if the patient is kept alive during the crucial period This applies to the use of epinephrine and Isuprel as well as the artificial cardiac pacemaker The cardiac pacemaker is unable to stop paroxysms of irregular ventricular tachycardia or ventricular fibrillation but is effective in shortening the ventricular standstill which may follow such paroxysms Because of impracticalities and the risk of fatal ventricular tachycardia fibrillation due to changing mechanisms of syncope the cardiac pacemaker is not recommended for short treatment of individual attacks of Adams-Stokes syndrome Prolonged stimulation after resuscitation is advised and has been carried out in 9 patients for periods of 25 minutes to 108 hours Douglas and Wagner[17] used a cardiac pacemaker continuously for seven days and effected recovery in a 72 year old man with Adams-Stokes syndrome and prolonged periods of ventricular asystole Untoward effects include chest pain, muscular twitch and superficial ulcerations under the chest electrodes

BUNDLE BRANCH BLOCK

Bundle branch block refers to a delay in or obstruction to the conduction of impulses in one of the branches of the bundle of His The obstruction may be complete or incomplete The terms intraventricular conduction defect and intraventricular block have been applied to electrocardiographic patterns believed to represent incomplete bundle branch block or multiple obstructions in the Purkinje fibers The term arborization block [49] formerly employed to denote extensive block in the arborization fibers of Purkinje has generally fallen into disuse Pathologic studies have thus far failed to disclose such distinct correlations between the anatomic findings and the electrocardiographic patterns The differentiation into complete bundle branch block incomplete bundle branch block and intraventricular block is essentially electrocardiographic

Chiefly on the basis of electrocardiographic findings a sharp division has been made into right and left bundle branch block Left bundle branch block has been reported to occur four to six times as often as right bundle branch block but more recent studies suggest that the stated predominance of left bundle branch block has been exaggerated [4] The higher incidence of left bundle branch block is related to the greater frequency of damage to the left ventricle Occasionally a complete block of both branches produces a condition identical with atrioventricular block [117, 96a]

The normal sinus impulse after traversing the a v node and bundle courses simultaneously through both bundle branches and their smaller ramifications In this way the excitation process reaches both ventricular cavities passes from the endocardial to the epicardial layer and activates both ventricles at the same time The QRS complex of the electrocardiogram represents the summation of the excitation process in both ventricles its normal duration is 0 06 to 0 09 second

If there is an obstruction in one of the main bundle branches e g the left the excitation process must travel along the (functionally) intact right branch the left ventricle is activated indirectly by passage of the impulse

from the right bundle branch through the interventricular septum to the arborization branches in the left ventricle The excitatory process travels much more rapidly through the specialized tissues of the conduction system than through the cardiac musculature Therefore about 0 04 to 0 05 second is lost in passage of the impulse to the left ventricle through the septal muscle instead of along the left bundle branch This delay in reaching the left ventricle is disclosed electrocardiographically by prolongation of the QRS complex while the abnormal route taken by the excitatory process is documented by an abnormal configuration of the QRS (aberrant QRS) Bundle branch block was produced experimentally and its electrocardiographic pattern described by Eppinger and Rothberger [2] The above classic description of the mechanism of bundle branch block has been contested by Sodi Pallares et al [113, 82] and by Burchell and associates[9] on the basis of experimental observations in the intact and isolated dog's heart respectively According to these studies the excitatory pathway in the ventricular system is from apex to base the left side being activated before the right and the apical portion of the right before the base

Bundle branch block may also be disclosed in many instances by asynchronism of ventricular contraction as seen by fluoroscopy or electrokymography or by simultaneous phonocardiograms and tracings of the carotid and jugular venous pulses [20, 101] In left bundle branch block there is a relative delay in the carotid pulse in right bundle branch block a relative delay in the v wave of the jugular venous pulse tracing

The Electrocardiogram

The essential features of bundle branch block are the *prolonged QRS interval* (0 12 second or more) the *slurring and notching of the QRS complex* and the delay in onset of the intrinsicoid deflection over the ventricle of which the bundle branch is blocked Thus in left bundle branch block the time between the onset of the QRS and the peak of R or R (intrinsicoid deflection) is prolonged in left precordial leads (0 05 second or more instead of normal up to 0 035 second), in right bundle branch block it is prolonged in right precordial leads (0 03 second or more instead of normal up to 0 02) Because of the abnormal course of the depolarization wave, the QRS may be bizarre, often resembling that of a ventricular premature beat

In left bundle branch block the initial septal activation is from right to left instead of left to right Hence there is no Q wave in left precordial leads as is usual normally Following septal activation the right ventricle and then the left ventricle is activated Except for the brief period when the right ventricle is being activated, right precordial leads are facing the negative side of the activation wave Hence they display a QS configuration or an rS if there is early dominance of right ventricular electromotive forces Left precordial leads show an RR′ configuration the first upright wave denoting septal and the R′ left ventricular activation

In right bundle branch block the septum is activated first from left to right then the left ventricle and finally the right ventricle is activated In right precordial leads there is an rSR complex denoting respectively the septal left ventricular and late right ventricular depolarization In left precordial leads there is an initial downward (q) wave for the left-to-right septal depolarization a tall upright (R) wave denoting right to-left (endocardial to-epicardial) left ventricular activation and a downward (S) wave for the final right ventricular left-to-right activation

This classic explanation of the electrocardiogram in bundle branch block namely that the initial portion of the R wave in precordial leads results from the transmission of septal potentials from the unblocked side through the septum cavity and ventricular wall of the blocked side, has recently been challenged by Kennamer and Prinzmetal[64] on the basis of intramural and intracavity potentials in experimental bundle branch blocks

The P wave and the P-R intervals are usually normal since the pathway of the sinus impulse is normal until it reaches the block in the bundle branch However it is not uncommon for bundle branch block to be associated with atrioventricular heart block and therefore with a prolonged P R interval [10] especially in left bundle branch block Occasionally an intraventricular conduction defect (with wide and notched QRS complexes) accompanies atrial fibrillation Under these circumstances P waves are absent but fibrillation "f" waves may be visible while the

QRS complexes occur at irregular intervals. With very rapid ventricular rates bundle branch block may be indistinguishable from ventricular tachycardia. The diagnosis of bundle branch block must always be made with caution during any paroxysmal tachycardia in which the P waves and P-R intervals are obscured.

Localization of Left and Right Bundle Branch Block. Since the earliest experimental studies of bundle branch block in dogs, the common bundle branch block pattern has been attributed to right bundle branch block and the uncommon form to left bundle branch block.[44] A host of observations have provided convincing and now generally accepted evidence that this nomenclature should be reversed. The confusion probably arose from the differences between the dog and human with regard to the relationship of the cardiac chambers to each other, to the chest wall and to the axis of the body. The position of the dog's heart is essentially vertical while that of the human is more horizontal or oblique.

Fahr[24] and also Mann[71] on theoretical grounds and Oppenheimer and Pardee[79] on the basis of pathologic studies first indicated that the accepted patterns for right and left bundle branch block should be reversed. Then Barker, Macleod and Alexander[2] by electrical stimulation of the right ventricle of the human heart exposed for drainage of a purulent pericarditis demonstrated that the main deflection of the QRS complex was upward in extrasystoles from that chamber. Since in a block of the left bundle branch the excitation process must pass from the right ventricle to the left, electrocardiographic pattern of left bundle branch block in any lead resembles that of a right ventricular extrasystole and of right bundle branch block that of a left ventricular extrasystole. According to the above observations, the common electrocardiographic form of bundle branch block formerly termed right bundle branch block is really due to a block of the left main bundle branch and is characterized by a major upward deflection in lead I.

By the use of unipolar precordial leads it became possible in doubtful instances to determine the presence or absence as well as the location of the bundle branch block.[116] Since activation of the myocardium underlying a precordial lead is denoted by a negative (intrinsic) deflection, this negative (S or QS) wave will be delayed if the electrode is placed on the side of the block. In left bundle branch block the descending limb of a broad R (i.e. the intrinsic negative) deflection is delayed in leads V_5 or V_6 while the negative deflection Q or QS occurs early in lead V_1 or V_2 over the right side of the precordium.

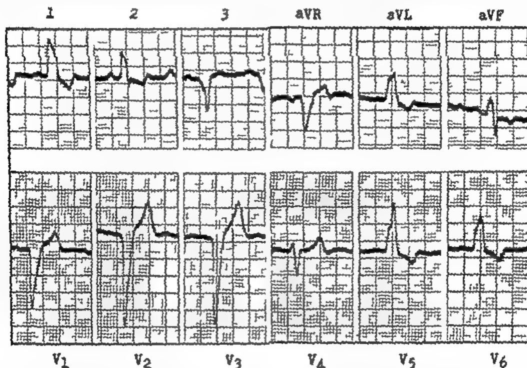

Fig. 92. Left bundle branch block in rheumatic mitral and aortic valvular disease.

Left Bundle Branch Block

The *typical pattern* in standard leads is *characterized by (Fig. 92)*:

1. QRS intervals of 0.12 second or more.
2. Conspicuous notching or slurring of the QRS complexes.
3. QRS complexes of discordant type with the major initial deflection (R) upward in

lead I and the major initial deflection downward in lead III There is no conspicuous [illegible] wave in lead I A Q wave seldom occurs in lead I[114] When it does it may be due to previous septal infarction to peri infarction block[29] to altered cardiac position during respiration or to other factors[44, 111]

4 Large T waves which are opposite in direction to the major ventricular deflections i e T is inverted in lead I and upright in lead III The S T interval is usually depressed in lead I and aV_L elevated in aV_F and lead III

However the electrocardiographic pattern of left bundle branch block may vary from this typical pattern but only as regards items (3) and (4) above Such variations are termed atypical bundle branch block The fact that we are dealing with left and not right bundle branch block is determined from precordial leads As a rule widening (0 12 plus second) and notching of the QRS complex with the major initial ventricular deflection upward in lead I denotes left bundle branch block (unless there [illegible] a broad S wave) The major initial deflection may also be upward in lead III (concordant curves) and the T waves may be deflected in the same instead of in the opposite direction to the main initial deflection in either lead I or III The reasons for these variations from the typical pattern and even for resemblances to the pattern of right bundle branch block are the presence of enlargement of one or both of the chambers of the heart the location and extent of associated myocardial damage and especially the position of the heart in the chest Discordant curves usually occur with normal or transversely placed hearts and concordant curves with vertically placed hearts In vertically placed hearts the pattern in the standard leads may tend to cause a left bundle branch block to resemble a right bundle branch block and a horizontally placed heart may cause right bundle branch block to simulate a block of the left branch[111]

Precordial leads in patients with *left bundle branch block* (Fig 92) are *most important for diagnosis* and are characterized by a delay in the onset of the intrinsic deflection (peak of R wave) in left precordial leads e g , V_5 and V_6 The peak of the R wave does not appear until 0 06 to 0 10 second after the beginning of the R wave instead of the normal of 0 02 to 0 05 second There is often [illegible] notched or M shaped R wave There is no Q wave in V_5 or V_6 because the septum is activated from right to left and the vector is directed *toward* the left precordial lead Over the right precordial leads e g V_1 and V_2 the R wave occurs normally 0 02 to [illegible] 03 second after onset of the QRS or there is an early onset of a deep QS When present the R wave is very small in the right precordial leads There is usually a large T wave

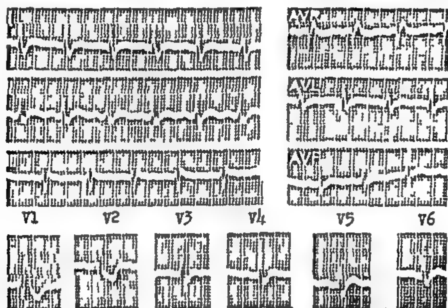

Fig 93 Right bundle branch block [illegible] type Intrinsic deflection (downstroke of R) delayed in V_1 and V_2 [illegible] in V_5 and V_6.

Right Bundle Branch Block

Typical right bundle branch block is characterized electrocardiographically in the standard leads by (Fig 93)

1 QRS complexes 0 12 second or more in duration

2 QRS complexes which are conspicuously notched or slurred

3 *A wide S wave in lead I* which most commonly is of lower voltage than the preceding slender R wave but may exceed the R wave in voltage Rarely there is a wide R wave in lead I

The main deflection in lead III is generally downward in horizontal hearts and upward in vertical hearts When S_1 is not very prominent S_2 and S_3 are

Many variations in the electrocardiographic pattern of right bundle branch block are caused by associated ventricular enlargement myocardial disease or differences in the electrical position of the heart According to the studies of Bayley[4] and of Wilson and his associates[134] there are four or five types of right bundle branch block pattern The commonest pattern of right bundle branch block is that designated as the wide S type or the Wilson block type[135] In this there is a tall slender R wave in lead I followed by a wide S wave of lower voltage and an upright T When this type occurs in a horizontal heart lead III is characterized by a deep Q wave or an rS deflection and an upright T whereas in a vertical heart lead III is characterized by an initial slender upright (R) wave a wide r and an inverted T

A variation of this type of Wilson block includes rare cases in which there is a wide S in lead III as well as in I and II and the wide S may dominate all the standard leads (concordant inverted type)

In the classic but relatively uncommon type of right bundle branch block there is a wide and often slurred S wave in lead I which exceeds the preceding r wave in voltage or there may be no R wave In lead III the main deflection is upward and consists of a slender initial R wave followed by a high positive slurred portion The major deflections in I and III are thus discordant and the T waves in these leads are opposite in direction to the major direction of the QRS (i e upright T_1 downward T_3)

Finally there is a so called unusual type of right bundle branch block[97] in which the R wave in lead I is not slender but as wide as the S wave when the latter is present S_3 is deep and wide and there is left deviation of the electrical axis in consequence this type may be mistaken for left bundle branch block on the basis of the limb leads On the other hand right sided precordial leads disclose late R or R deflections and aV_R shows a qR deflection indicating right bundle branch block However recent vectorcardiographic studies by Richman and Wolff[10] reveal that these cases are actually instances of left bundle branch block with extensive septal and inferolateral infarction

The *precordial leads in right bundle branch block* are of special diagnostic importance The characteristic findings are (Fig 93)

1 R waves which are prominent in leads V_1 V_2 (right side of heart) and which occur late The peak of the R wave occurs 0 04 to 0 10 second or more after the beginning of the QRS instead of the normal of 0 02 to 0 03 second The R wave is broad and notched and often bifid in which circumstance it has been found that the second peak corresponds to the R wave peak in other precordial leads A prominent R wave in right precordial leads occurs not only in right bundle branch block but also in right ventricular hypertrophy without conduction disturbance and in cases of myocardial infarction involving the lateral wall of the left ventricle[1] A prominent Q in these leads suggests septal infarction but a small q may precede a tall slurred and wide R in leads V_1 and V_2 in the uncommon classic type of right bundle branch block

2 Slender R waves which are prominent in leads from the left side of the heart (V_5 V_6) but which occur early The peak of R_5 or R_6 occurs 0 02 to 0 05 second after the beginning of the QRS complex The R wave is usually followed by a broad shallow S The ST segments are usually depressed over the right precordium and elevated over the left precordium The T waves are usually inverted over the right and upright over the left precordium

Incomplete Bundle Branch Block Intraventricular Conduction Defects[7 116]

These terms have been applied to electrocardiographic patterns resembling bundle branch block in which

1 The QRS interval is 0 10 to 0 11 second This is believed to denote some delay in or incomplete obstruction to conduction

through the main bundle branches or their ramifications

2 The QRS complexes are often notched or slurred When present this suggests a deviation from the normal pathway of excitation of one or both of the ventricles

Incomplete Left Bundle Branch Block

When the above pattern resembles that of left bundle branch block i e, the main deflection is upward in lead I downward in lead III with T waves in opposite direction but the QRS interval measures only 0 10 to 0 11 second it may be termed incomplete left bundle branch block The R and S waves are usually of higher voltage than in complete bundle branch block and there is no notching at their peaks

In some electrocardiograms of patients with marked left ventricular enlargement the pattern is that of left axis deviation (p 108) and the QRS interval measures 0 10 to 0 11 second This combination may be indistinguishable from incomplete left bundle branch block The prolonged QRS interval may represent the longer period required to activate the enlarged left ventricle However, precordial leads will not disclose the delay in appearance of the peak of the R wave when the leads are applied over the left side of the heart (V_5 V_6)

Incomplete Right Bundle Branch Block

This is characterized by an rR′ pattern in V_1 and V_E in which the second R wave (R′) is separated from the first by 0 01 to 0 03 second a prominent or widened S wave in left precordial leads (V_6) and a QRS duration of 0 10 in standard and up to 0 11 second in precordial leads [4]

Incomplete bundle branch block may be associated with conditions producing strain or damage to the right ventricle [14] especially congenital heart disease rheumatic mitral disease pulmonary disease with cor pulmonale and coronary disease with ventricular septal infarction [110] Changes in position and conformation of the heart may occasionally produce the above pattern in the absence of delayed intraventricular conduction Differentiation of the electrocardiographic pattern of incomplete right bundle branch block due to right ventricular hypertrophy and that due to defective conduction is facilitated by vectorcardiography (p 118) [55]

The association of right ventricular hypertrophy with incomplete right bundle branch block may be denoted by a very tall R′ wave in V_1 and a very deep S in V_6 And associated left ventricular hypertrophy may be documented by a very tall R in V_6

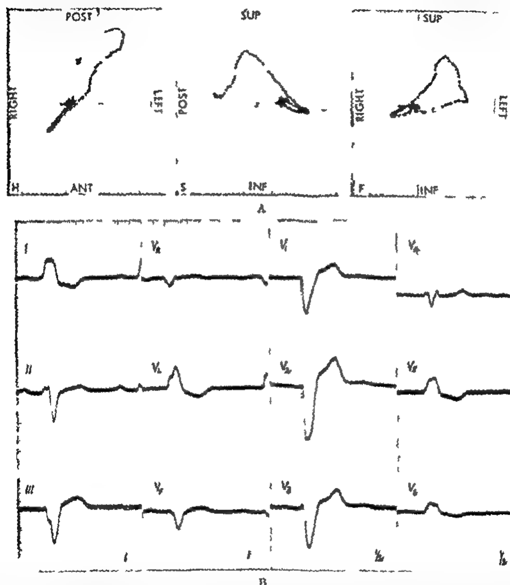
Vectorcardiogram in Left Bundle Branch Block[33 105] (Fig 91)

Since the ventricular septum is activated from right to left by way of the functioning right bundle and the free right ventricular wall is activated early, the initial QRS vectors are directed downward to the left and somewhat posteriorly These *initial vectors* in addition to close spacing of the time markings of the QRS loop, are the characteristic feature of left bundle branch block and remain constant even in the presence of associated heart disease such as myocardial infarction The initial vectors account for the initial positive deflections in the left precordial leads and in the inferior lead e g V_F and V_E (since the vectors are directed inferiorly and to the left) and for the initial negative deflections in the superior leads aV_R and aV_L and for the initial negative deflections (Q waves) in right precordial leads The time markings are very close, particularly in the middle and distal portions of the QRS loop

In the horizontal projection, the QRS loop is inscribed in a clockwise direction, instead of counterclockwise as occurs normally The long axis of the loop usually lies between minus 30 and minus 60 in the horizontal projection The loop usually fails to close and the ST vector is directed to the right anteriorly and inferiorly resulting in ST elevations in right precordial leads (V_1, V_2) and depressions in aV_L I and left precordial leads V_5 and V_6 The T wave is usually oriented at an angle of approximately 180 degrees to the QRS loop, consequently the T wave is directed opposite to the main deflection of the QRS in the electrocardiogram In some cases the QRS loop in the horizontal projection shows a small initial deflection anteriorly directed resulting in a small positive deflection (r) in right precordial leads In these cases the loop is usually figure of 8 in conformation with the large distal portion inscribed in a clockwise direction

The vectorcardiogram has been helpful in distinguishing left bundle branch block from left ventricular hypertrophy especially in occasional instances of the latter in which the QRS is 0 12 second or longer The vectorcardiogram of left bundle branch block

differs from that of left ventricular hypertrophy in (1) the close spacing of the time markings in the former (2) the inscription of the horizontal QRS loop in left bundle branch block in a clockwise instead of in a counterclockwise direction and (3) the inscription of the *initial part* of the horizontal QRS loop to the left and posteriorly in left bundle branch block to the right and anteriorly in left ventricular hypertrophy



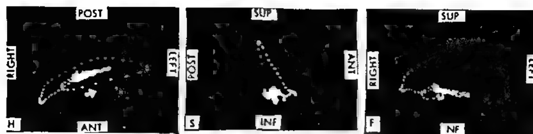


Fig 94 *A* Vectorcardiogram indicating left bundle branch block The vectorcardiogram is inscribed clockwise in the horizontal plane and is directed posteriorly superiorly and to the left Conduction delay is indicated by increased proximity of the time markings in the middle and late portions of the QRS loop H—horizontal S—sagittal F—frontal plane projection

B Electrocardiogram of same patient at speed of 50 mm per second

The Vectorcardiogram in Right Bundle Branch Block (Fig 95)

The Wilson type of right bundle branch block is characterized chiefly by increased duration and slow irregular contour of the *terminal portion* of the QRS spatial vector (SE) loop[54,3] The delay in activation is denoted by *close spacing of the time markings* The terminal portion of the QRS loop forms an appendage directed to the right and an

A

B

Fig 95 *A* Vectorcardiogram indicating right bundle branch block. The initial portion of the QRS is normally inscribed counterclockwise in the horizontal plane projection but terminal portion is irregular slowly inscribed (close time-markings) and forms appendage oriented to the right and anteriorly T loop is directed opposite to this QRS appendage H—horizontal S—sagittal F—frontal plane projection

B Electrocardiogram of same patient.

teriorly whereas the T loop axis is directed opposite to that of the terminal portion of the QRS loop This terminal appendage of the QRS is present even in the presence of associated left ventricular hypertrophy or myocardial infarction In the *classic rare form of right bundle branch block* there is similar close spacing of the time markings, especially of the terminal portion but this may occur throughout the QRS loop The QRS loop is directed to the left downward and anteriorly and is open The latter results in a positive ST vector directed upward posteriorly and to the left which is disclosed electrocardiographically by ST elevations in aV_R and aV_L and left precordial leads and depression in aV_F III and right precordial leads

The *vectorcardiogram* may be useful in the differential diagnosis between left or right incomplete bundle branch block which is due to conduction disturbance and that due to left or right ventricular hypertrophy[11] (p 118)

Recurrent (Paroxysmal) and Intermittent Bundle Branch Block

When bundle branch block appears temporarily but continuously for hours or days we speak of it as paroxysmal bundle branch block Recurrent attacks of bundle branch block have been described repeatedly[103, 111, 84] Such recurrent attacks may be functional in cases of tachycardia without underlying cardiac disease or they may occur in cases of organic heart disease in which a variety of factors impair the conductivity of the conduction system As a rule recurrent bundle branch block occurs in patients with recent or old myocardial infarction or chronic coronary and hypertensive heart disease

Occasionally QRS complexes denoting bundle branch block alternate with normal QRS complexes or they may appear more or less regularly in ratios of 1 1 1 2 or 3 2 block etc the first figure representing the number of normal complexes and the second the corresponding number of block complexes Such curves are termed intermittent bundle branch block They probably result from partial block or defective bundle branch conduction of variable degree Cases of intermittent or unstable bundle branch block have been described in which the presence of the block or of normal conduction depended on whether the ventricular rate exceeded or fell below a critical value[127, 111] The critical rate may be within normal limits or within the range of bradycardia or tachycardia Sometimes there is a progressive change from normal to typical QRS complexes of the branch block variety resembling the Wenckebach phenomenon of partial atrioventricular block with dropped beats Presumably the conduction time through the bundle branch increases gradually until there is a block This permits recovery of the bundle branch and the next impulse passes normally and so on seriatim

Etiology and Pathology

In the great majority of cases of bundle branch block the probable cause is coronary atherosclerosis with recent or old occlusion and associated hypertension The bundle branches may be damaged and blocked by acute infarction and subsequent fibrosis Or a more gradual degenerative and fibrotic alteration may be due to chronic coronary atherosclerosis with myocardial ischemia

Pathologic and electrocardiographic correlations are often uncertain owing to the paucity of studies and especially to technical difficulties Often there is no correlation between the vessels occluded the site of infarction and the type of branch block In some cases of typical bundle branch block as seen in the electrocardiogram serial sections of the atrioventricular conduction system showed no anatomic lesion of the bundle branches[102] Lesions may be found involving both branches[145] especially in extensive septal infarction Right bundle branch block like left bundle branch block may be due to an isolated septal lesion interrupting the single branch[81, 84] Because the right bundle branch receives its blood supply from early perforating branches of the left coronary artery and because of its superficial location below the anterior septal surface the right bundle branch may be blocked in mild anteroseptal infarction However in posterior wall infarction it is not apt to be involved unless there is extensive septal infarction[84]

Left bundle branch block or right bundle branch block may occur in the absence of apparent cardiac disease but this is much more common with right bundle branch block[147] About 25 to 50 per cent of cases of right bundle branch block are unaccompanied by symptoms or signs of organic heart disease but the incidence is less in series of cases observed in a cardiac clinic or observed because of suspected cardiac disease Probably

90 per cent or more of the patients with organic heart disease and left bundle branch block have coronary and hypertensive heart disease or aortic valvular disease especially calcific aortic stenosis

Among cases of right bundle branch block with organic heart disease about 75 per cent are due to coronary and hypertensive heart disease about 15 per cent to rheumatic cardiovalvular disease 3 per cent to acute or chronic cor pulmonale about 3 per cent to congenital heart disease and smaller numbers to other rarer causes When rheumatic mitral stenosis is associated with bundle branch block the pattern is usually that of right bundle branch block [4]

Incomplete right bundle branch block is associated most frequently with congenital heart disease (especially interatrial septal defect or pulmonic stenosis) and with mitral valvular disease but coronary and hypertensive heart disease and chronic cor pulmonale also account for many cases In one-quarter to one-half the cases of incomplete as in complete right bundle branch block, there may be no apparent organic heart disease

Other causes of bundle branch block are syphilitic gumma or luetic aortitis with gummatous myocarditis diphtheria tumors cysts trauma bacterial endocarditis and perhaps other bacterial or viral infections or myasthenia gravis Quinidine procaine amide and digitalis may cause a toxic impairment in bundle branch conduction A toxic bundle branch block may occur in uremia and hyperkalemia [7] Bundle branch block has *occurred as a temporary phenomenon in* thyrotoxicosis [8] Functional disturbance may result from any severe paroxysmal tachycardia and atrial flutter with subsidence as the rate slows and from acute right ventricular strain due to massive pulmonary embolism Four cases of persistent right bundle branch block following pulmonary valvulotomy and infundibular resection were reported [45] There was also a report of 4 cases of benign left bundle branch block in two generations of one family of 13 living members [14]

The *age and sex* of patients with bundle branch block is determined by the cause Since coronary atherosclerosis is the chief cause bundle branch block is observed mostly among males beyond the age of 50

Clinical Features and Diagnosis

There are no symptoms of bundle branch block as such But there may be symptoms of the causative disease Likewise there are usually no specific diagnostic signs Occasionally bundle branch block is associated with paroxysmal or persistent heart block and syncopal attacks of the Adams-Stokes type [120] A palpable reduplicated apical impulse,[47] prolongation or splitting of the first sound and reduplication of the second sound, all due to slightly asynchronous contraction of the ventricles,[131] may suggest the presence of bundle branch block but as a rule the diagnosis is not made on physical examination Bundle branch block is not infrequently associated with a diastolic gallop rhythm and occasionally with pulsus alternans The latter two findings should suggest the possibility that bundle branch block is also present especially if the heart rate is less than 90 per minute

The definite diagnosis of bundle branch block however, depends on electrocardiographic study (p 396) The diagnosis is indicated primarily by the relatively late time of onset of the intrinsicoid deflection as seen in precordial leads and by the prolonged duration of the QRS complexes in standard leads

Course and Prognosis

Bundle branch block occurs transiently or may persist permanently When due to toxic factors which may be removed bundle branch block is a temporary reversible condition Intraventricular block associated with the paroxysmal tachycardia of atrial flutter subsides when the paroxysm ceases The bundle branch block associated with severe coronary atherosclerosis and other forms of organic heart disease is usually persistent but I have several times seen bundle branch block develop at the onset of an acute coronary occlusion and disappear within a few days Bundle branch block may recur intermittently for a period of months and then disappear or become permanent [51] Kalett[43] reported a case of bundle branch block with spontaneous remission after four years and Myre and Fuller[75] after at least three years But as a rule when the branch block persists without remission for several months it is likely to be permanent

Too much importance has been attached to the prognostic significance of bundle branch block It has been stated that the survival

period averaged one to two years although more recently it has been recognized that some patients with this condition survived five to twenty five years or longer [85, 1, 8] Actually the prognosis depends on the underlying cause [112] The unfavorable prognosis usually applied to bundle branch block corresponds to the prognosis of coronary occlusion which is the commonest cause As in recent years we have become aware that the prognosis of coronary occlusion is more optimistic than was formerly thought there has been a correspondingly more favorable outlook for bundle branch block Furthermore bundle branch block occurs more frequently in the younger age right or left ventricular damage and especially in cases of coronary heart disease Papp and Smith[81] recently called attention to the changing electrocardiogram in the Wilson type of right bundle branch block and emphasized that except in rare instances it is a sign of organic heart disease In general it is safer to evaluate the patient and his disease as a whole rather than to base a prognosis on the presence and type of bundle branch block

Treatment

Treatment is directed toward any underlying or associated condition The presence of bundle branch block in itself is no indication for treatment However when it results from

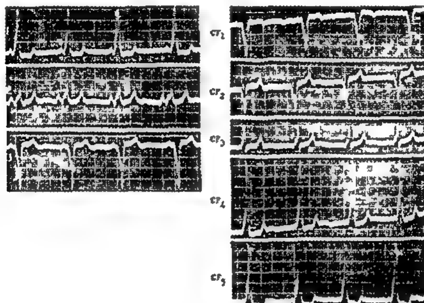

Fig 90 Wolff Parkinson White syndrome Short P R interval with bundle branch type of QRS (0 13 second in lead I)

groups than was formerly believed in these there is no apparent evidence of heart disease and the outlook is benign [85]

Right bundle branch block is considered to offer a more favorable prognosis than left bundle branch block [8, 116] Such generalization must be accepted with caution especially in view of the uncertainties as to the interpretation of patterns now believed to represent right bundle branch block In the series of cases studied by Taimont et al [105] right bundle branch block of the classic or rare type was found only in cases with clinical and anatomic evidence of severe right ventricular involvement whereas the Wilson or S type was equally distributed among cases with digitalis or quinidine or other intoxication the causative agent should be eliminated if possible

SHORT P R INTERVAL WITH WIDE QRS (WOLFF PARKINSON WHITE SYNDROME)

Electrocardiograms resembling those of bundle branch block but with a short P R interval have been repeatedly noted in young and apparently healthy individuals who are subject to attacks of paroxysmal tachycardia Isolated cases were documented by Wilson[133] and others [22] but interest became widespread only after Wolff Parkinson and White[111] in 1930 reported 11 cases and defined the condition as a distinct entity For this reason it is

often termed the Wolff Parkinson White (W-P-W) syndrome [140] In 1940 Hunter et al [38] collected 90 cases from the literature and added 19 of their own

The essential diagnostic feature is a *distinctive electrocardiogram* (Fig 96) in which QRS complex Consequently the interval from the onset of the P wave to the end of the QRS (P-J interval) remains normal QS deflections in leads II, III and right precordial leads, ST deviations and T wave abnormalities may occur The electrokymogram usually shows a

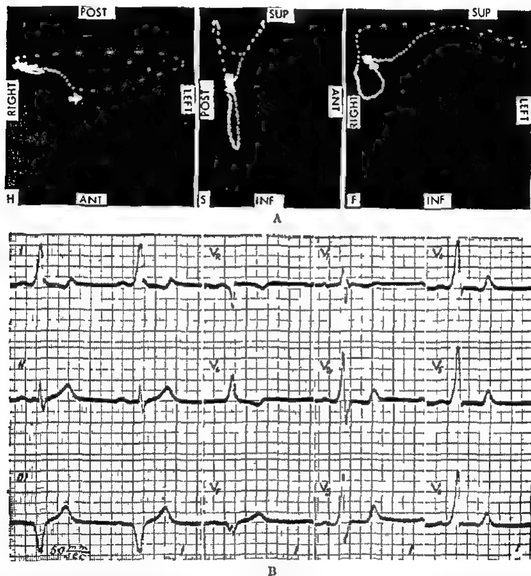

Fig 97 *A* Vectorcardiogram indicating Wolff Parkinson White syndrome in a 16 year old boy with coarctation of the aorta Characterized by very slow (closely spaced) initial segment of QRS loop H—horizontal S—sagittal F—frontal plane projection

B Electrocardiogram of same patient

(1) the P-R interval is abbreviated, measuring 0 10 second or less (2) the QRS complexes are widened (0 11 to 0 14 second) and slurred, (3) there is *slurring* at the onset of the upstroke of the R wave, termed the *delta wave* The shortening of the P-R interval is exactly compensated by the widening of the delay in contraction of both ventricles and occasionally ventricular asynchronism,[100] but this requires further study The *vectorcardiogram* of the Wolff Parkinson White syndrome is characterized by close spacing of the time markings of the initial (centrifugal) portion of the QRS loop[31] (Fig 97)

An essential clinical feature is the tendency to recurrent attacks of paroxysmal atrial tachycardia or atrial flutter Occasionally atrial fibrillation occurs Ventricular tachycardia has also been reported in cases of Wolff Parkinson White syndrome [61 18] but may have represented an instance of atrial flutter with aberrant conduction resembling ventricular tachycardia The Wolff Parkinson White syndrome should be sought in every case of paroxysmal supraventricular tachycardia Jones[41] discovered the Wolff Parkinson White syndrome in 5 of 47 cases of paroxysmal atrial tachycardia and in 4 others there was a probable variant of the syndrome

The characteristic electrocardiographic Wolff Parkinson White pattern is sometimes termed the anomalous mechanism anomalous atrioventricular excitation or preexcitation syndrome This Wolff Parkinson White pattern may be continuous but there is often a spontaneous or induced transformation of the electrocardiogram to a normal P R interval and normal QRS width There may be isolated Wolff Parkinson White beats or Wolff Parkinson White beats alternating with normal complexes There may be progressive widening of the QRS complexes as the P R interval shortens or the widened QRS and narrow P R may gradually return to normal (concertina effect)

The distinctive electrocardiographic features may disappear spontaneously as a result of atropine quinidine procaine amide or amyl nitrite or when the heart rate is increased by exercise In the case reported by Wilson [133] that of a man aged 23 years the electrocardiographic abnormalities appeared after stimulating the carotid sinus or spontaneously When they appeared spontaneously they could be abolished by the administration of atropine Subsequent reports have been conflicting as to the regularity with which the electrocardiographic changes can be eliminated by atropine and exercise Quinidine[92] and large doses of digitalis[104] have been observed to restore a normal electrocardiogram in some cases but in another case digitalis widened the QRS complex [87]

When persons with the Wolff Parkinson White syndrome experience a paroxysm of tachycardia the widened ventricular complexes assume a normal configuration but occasionally they remain aberrant [74] During paroxysms of atrial fibrillation the QRS complexes appear aberrant and may be wider than during periods with sinus rhythm [73] but the absence of P waves during atrial fibrillation prevents a differentiation of wide QRS complexes of the W P W syndrome from those due to true bundle branch block or ventricular extrasystoles The Wolff Parkinson White syndrome may be suspected from the delta wave in the wide QRS complexes The QRS of the W P W syndrome may conceal the Q waves associated with cardiac infarction and it may also obscure the pattern associated with ventricular hypertrophy or right bundle branch block But spontaneous suppression of the Wolff Parkinson White complexes may reveal these changes [14]

Atypical Forms of Wolff Parkinson White Syndrome

A variety of modifications of the Wolff Parkinson White syndrome have been described There may be a short P R interval with normal QRS complexes and episodes of supraventricular tachycardia [87] These were usually observed in middle-aged females devoid of organic heart disease But there has been reported also the occurrence of short P R intervals with normal QRS complexes in coronary thrombosis hyperthyroidism hypertension and in neurotic individuals presumably owing to altered autonomic tone In Oehnell s series of 200 cases with a short P R interval [77] there was a greatly increased incidence of paroxysmal tachycardia whether the QRS was widened as in the Wolff Parkinson White syndrome or of normal width But the incidence of paroxysmal tachycardia was 25 per cent in the former and 10 4 per cent in the cases with a short P R interval and normal width of QRS

In other cases [6] the P R interval may be 0 12 second and the QRS of normal width but the initial portion of the R wave is slurred (delta wave) Other variants have been described by Bordnas et al [7]

Etiology

The Wolff Parkinson White syndrome occurs at all ages but chiefly below the age of 30 and more commonly in males It has been observed with increasing frequency among infants and children [117 21] There is evidence that the mechanism producing the Wolff Parkinson White syndrome may be latent for many years[68] and may be first demonstrated in later life For these reasons and

because the subjects are apparently healthy, aside from the paroxysmal tachycardia, it is deemed probable that the Wolff-Parkinson-White syndrome is of congenital origin. This concept is also supported by reports of the occurrence of the W-P-W syndrome in siblings.[1]

On the other hand, the *electrocardiographic pattern* of the Wolff-Parkinson-White syndrome has been produced in animals by injecting various chemicals or otherwise stimulating the ventricular septum or other parts of the ventricular myocardium[87] and in humans by cardiac catheterization[50, 3] and after intravenous strophanthin.[15] But it is questionable whether these represent an identical mechanism with that of the Wolff-Parkinson-White syndrome.

Mechanism

The mechanism responsible for the W-P-W syndrome is uncertain, although several theories have been offered.[27, 35, 139, 77, 110, 73, 87, 86] Wolff, Parkinson and White[141] attributed the electrocardiographic changes to excessive vagal tone because they could abolish them with atropine or exercise and because occasionally the electrocardiographic abnormalities could be induced by vagal stimulation. This theory was rejected because these effects of atropine or vagal stimulation could not be confirmed in many other cases and because the electrocardiographic changes could not be harmonized with the known effects of vagal stimulation. The various theories attempt to explain the premature activation of a small portion of ventricular musculature (preexcitation) which accounts for the short P-R interval, the delta wave and the wide QRS. The theories propose either (1) anomalous conduction which avoids the delay in passage through the normal a-v node or (2) anomalous impulse formation whereby an irritable septal focus below the atrioventricular node is prematurely excited by electrical or mechanical stimuli from the atrium.[110, 77] The first of these theories has several variants according to the route of anomalous conduction: (a) an accessory muscular or neuromuscular pathway between atria and ventricles[27, 139], (b) along the atrioventricular groove and through the ventricular wall from epicardium to endocardium[2], (c) through a disordered portion of the atrioventricular node which permits accelerated conduction.[87]

The most generally accepted theory is that of Holzmann and Scherf[27] and of Wolferth and Wood[139] who postulated the existence of an anomalous aberrant pathway between the atria and ventricles by which the sinus impulse activated the latter chambers. Wolferth and Wood[139] suggested that this aberrant pathway might be similar to the so-called bundle of Kent, a structure in the heart of the rat, bridging the atrioventricular groove.[46] Subsequently this hypothesis received support by the postmortem discovery of such an accessory bundle in the heart of a child who had exhibited this syndrome during life and who died during an attack of paroxysmal tachycardia.[144] (See also Oehnell.[77]) Histologic demonstration of an accessory right lateral conduction bundle was reported also in a case of septal infarction with complete heart block and intermittent anomalous a-v excitation (W-P-W syndrome[40]). (Normally there are no accessory communications outside the conduction system between atria and ventricles.[59]) The theory of an accessory pathway was also supported by the experimental production[9] of a short P-R with wide QRS when the normal conduction system was short circuited by a vacuum tube amplifier analogous to the alleged short circuiting effect of an accessory conduction bundle. By reversing the connections so that amplified ventricular currents stimulated the atria, paroxysms of tachycardia were induced. Although it is usually believed that the aberrant short conduction pathway connects the right atrium and right ventricle, there are cases of W-P-W syndrome in which the left ventricle is activated before the right.[89, 118]

According to the theory of Wolferth and Wood,[139] the short P-R interval is due to the shorter, more direct pathway through the accessory bundle from the atrium to the ventricle while the prolongation of the QRS results from premature activation of one ventricle. The altered configuration of the QRS especially in its early portion is attributed to the abnormal course of the impulse when it first reaches the ventricle. The anomalous pathway is said to predispose to attacks of paroxysmal tachycardia by facilitating retrograde conduction of the impulse (reentry) into the atrium where under favorable circumstances the abnormal rhythm is initiated. Fox and associates[3] offered the hypothesis that supraventricular arrhythmias

result from a block of the aberrant bundle due to a decrease in "vagus substance" An ectopic focus in the supraventricular portion of the aberrant bundle above the block gives rise to impulses which activate the ventricles by way of the normal bundle

Recently Prinzmetal and associates[27] have marshalled experimental and clinical evidence indicating that the Wolff Parkinson White syndrome results from a disturbance in the atrioventricular node In consequence the normal slowing of conduction through the node is impaired and conduction of the impulse is accelerated through the abnormal part of the node rather than through an abnormal bundle The part of the ventricular myocardium stimulated by the accelerated portion of the impulse is activated earlier than the remainder of the ventricular myocardium which is stimulated by the normal slower portion of the impulse According to Prinzmetal the nodal defect sometimes functions as an ectopic focus to give rise to various supraventricular arrhythmias notably atrial tachycardia but also atrial flutter and fibrillation

Clinical Features and Prognosis

There is no distinctive clinical picture except for the occurrence of supraventricular tachycardia in the vast majority The Wolff Parkinson White syndrome is often the basis of the paroxysmal tachycardias in infancy and childhood There may be a split first sound at the apex a systolic murmur and sinus arrhythmia Although the subjects with Wolff Parkinson White syndrome are almost always free of organic heart disease reports of coronary and other heart disease have appeared repeatedly in recent years[25, 119] but these are coincidental The condition is not always benign even in the absence of organic heart disease for deaths have occurred suddenly in the course of an attack of paroxysmal tachycardia[25] Some patients suffer disability because of frequent recurrent attacks of tachycardia and its attendant symptoms The syndrome is not a contraindication to normal activity pregnancy operations and the like

Diagnosis

The diagnosis of Wolff Parkinson White syndrome is made by observing the characteristic electrocardiographic changes (p 406) However it is often overlooked and therefore should be carefully sought in (1) all patients with paroxysmal tachycardia (2) when the electrocardiogram suggests bundle branch block (3) whenever there is slurring of the initial portion of the R wave (4) when the P R interval is 0 10 to 0 12 second or less (5) when there are spontaneous changes in the duration of the P R interval and QRS (6) when there appear to be runs of ventricular tachycardia during paroxysms of atrial fibrillation[140]

The electrocardiographic pattern of the Wolff Parkinson White syndrome is often misinterpreted to denote heart disease especially myocardial infarction bundle branch block or ventricular hypertrophy This will be usually avoided if the P R interval is carefully measured in the three standard leads

Management of Wolff Parkinson White Syndrome

The electrocardiographic pattern of the Wolff Parkinson White syndrome requires no treatment The patient should be reassured The various forms of supraventricular tachycardia should be treated as in other patients without the Wolff Parkinson White syndrome In cases of paroxysmal atrial fibrillation in which digitalis would ordinarily be effective in slowing the ventricular rate this drug is usually ineffective when there are constant runs of aberrant ventricular beats resembling ventricular tachycardia These should be treated with quinidine which tends to suppress the anomalous mechanism and may also eliminate the atrial fibrillation

PART IV

DISEASES OF THE CORONARY ARTERIES AND CORONARY HEART DISEASE

Chapter 16

CORONARY (ATHEROSCLEROTIC) HEART DISEASE, OTHER DISEASES OF THE CORONARY ARTERIES

Atherosclerosis is by far the commonest lesion of the coronary arteries Sooner or later in varying degree most hearts are thus affected But only in the minority of cases does coronary atherosclerosis evoke significant myocardial lesions or clinical disturbances of the heart For this reason coronary atherosclerosis is an undesirable term when used to express a clinical form of heart disease

To obviate this confusion the term coronary heart disease has been suggested to represent clinical heart disease due to lesions of the coronary arteries But this is satisfactory usage only if it is recognized that the cardiac disease may be due occasionally to other coronary disturbances besides coronary atherosclerosis e g, syphilitic coronary ostial stenosis The term atherosclerotic heart disease may be employed to designate the various clinical cardiac manifestations due to coronary atherosclerosis and its anatomic cardiac sequelae Atherosclerotic heart disease coronary heart disease and coronary atherosclerotic heart disease are terms commonly used interchangeably The degenerative atheromatous sclerotic and calcific alterations of the endocardium and valves should not be classified as or confused with atherosclerotic heart disease They are essentially purely pathologic lesions the nature of which can clearly be indicated by terms which do not include the words heart disease

This chapter encompasses a general survey of the subject of coronary heart disease Angina pectoris coronary thrombosis and myocardial infarction are almost always intrinsic elements of coronary heart disease but they require sufficiently detailed discussions to justify independent chapters which follow This segregation should not obscure their relation to the general heading of coronary heart disease

INCIDENCE OF CORONARY HEART DISEASE

Coronary heart disease is the commonest form of clinical heart disease beyond the age of 40 With the progressive aging of our population cardiovascular disease has become more definitely the dominant cause of death and coronary heart disease the major form of fatal cardiac disease

The most reliable studies of the incidence of coronary heart disease are those concerned with well defined manifestations such as angina pectoris or acute myocardial infarction (Chaps 17-21) Pathologic evidence indicates that coronary atherosclerosis of variable degree increases progressively with age up to the age of 60 in men [4] and 80 in women [1] But clinical manifestations occur only when it leads to extreme narrowing or occlusion of the lumen of a major coronary branch Among young soldiers killed in action in the Korean war with an average age of 22 years 77 3 per cent had gross pathologic evidence of coronary atherosclerosis [44] But only 10 per cent exhibited advanced disease with more than 70 per cent of the lumen of a major vessel occluded The diagnosis of coronary (atherosclerotic) heart disease refers to clinical manifestations and not to the mere presence of atherosclerotic lesions Extensive pathologic lesions may be present but cannot be diagnosed unless they produce overt clinical manifestations

ETIOLOGY OF CORONARY (ATHEROSCLEROTIC) HEART DISEASE

Underlying Cause

Atherosclerosis of the coronary arteries and the consequent disturbances in the blood supply to the myocardium compose the underlying cause of coronary (atherosclerotic) heart disease Unfortunately our understanding of the genesis of atherosclerosis is still in

adequate The theories offered to explain the pathogenesis of atherosclerosis are discussed below

Predisposing and Contributing Causes

Age and Sex Both the pathologic lesions and the clinical forms of coronary heart disease occur predominantly after the age of 40 and with increasing frequency in subsequent decades In a study of 865 cases of coronary artery disease, Peel[165] found that in men the incidence is significant earlier than in women reaches a high peak at 55 to 59 and thereafter falls steeply In women the rise in incidence is slow and steady from the age of 40 to 70 without an ultimate fall However, instances of advanced coronary heart disease are not rare before the age of 40[59, 242] and the incidence of coronary occlusion in young persons appears to be increasing This has been notable in civilian practice[64] as well as in the armed forces[54] Gertler Garn and White[70] found that 100 young persons with proven coronary heart disease were characterized by a 'resolute and intensive personality' a stocky physique a serum cholesterol level above 309 mg per 100 cc, a serum uric acid above 5 4 mg per 100 cc and a high serum cholesterol phospholipid ratio[70]

Coronary heart disease [illegible] much more frequent among males than among females, but this predominance does not prevail among diabetic patients and is less striking in the presence of hypertension and among subjects beyond the age of 60 [illegible] [15] A satisfactory explanation of atherosclerosis should account for this striking difference in incidence between males and females and the equalizing effect of diabetes and hypertension

Hypertension is found in about 50 per cent of men and in about 75 per cent of women with coronary heart disease[15] Conversely there is a high incidence of coronary heart disease in patients with hypertension[4, 55] Induced hypertension increased the severity of experimental atherosclerosis in rabbits[20] dogs[20] and chicks[10] (But the frequency of coronary heart disease in the absence of hypertension indicates that hypertension is only an accessory or aggravating factor in atherosclerosis and not a primary cause (p 428))

Diabetes Coronary heart disease develops with unusual frequency among diabetic patients and at a relatively earlier age than among non diabetics[18, illegible, 3, illegible, 55] A similar relationship has been noted to familial xanthomatosis with hypercholesterolemia (p 425) Essential hyperlipemia is also associated with premature atherosclerosis Myxedema, chronic glomerulonephritis and obesity are some of the other conditions which have been said to predispose to coronary heart disease

Heredity The occurrence of coronary heart disease in several members of a family is a common observation There are insufficient formal studies and statistical data to justify the conclusion that heredity is an important factor in coronary heart disease But Thomas and Cohen[214] found that clinical coronary artery disease was nearly four times as frequent among siblings of persons with coronary disease as among siblings of persons without it

Body Type Studies of body type have suggested that individuals of the so-called mesomorphic type i e with predominant maleness muscularity and compactness' are most apt to develop clinical coronary atherosclerosis as indicated by myocardial infarction before the age of 40[65] and by necropsy studies of the coronary arteries in males under the age of 46[197]

Obesity There is indirect evidence, based chiefly on life insurance[45] and autopsy statistics[59, 230] that obesity predisposes to fatal coronary atherosclerosis According to life insurance data the mortality from coronary heart disease in obese individuals is 40 per cent higher than among standard risks[45] On the other hand Gertler and associates[67] found that obesity alone was no more common among young men with coronary disease than among other men of the same age and social status Faber and Lund[65] found that obesity had no effect on the development of aortic atherosclerosis in the human if the influence of hypertension was taken into account

Smoking Recently indirect evidence has been accumulating that there is a relationship between smoking and coronary heart disease[90] According to Hammond and Horn[88] there was a 56 per cent increase in mortality over the expected rate in regular cigarette smokers and this increase was even more striking with respect to deaths from coronary heart disease

Dietary Geographic and Ethnic Factors are discussed in connection with the pathogenesis of atherosclerosis (p 426) Coronary heart disease is said to be uncommon among the Chinese Japanese Okinawans Bantu tribes

men in South Africa[155] and others Gilbert[71] found no coronary heart disease among the Navajo Indians in Arizona although the disease is common in other persons in the same area

For additional discussion of some of the above etiologic factors in coronary heart disease see the chapters on angina pectoris (p 449) and acute myocardial infarction (p 493)

DEFINITION AND CLASSIFICATION OF ARTERIOSCLEROSIS

The term arteriosclerosis (hardening of the arteries) refers to a variety of degenerative vascular changes which are best defined by a description of the pathologic alterations The changes due to syphilis rheumatic fever specific infectious diseases thromboangiitis obliterans periarteritis nodosa lupus erythematosus among others are not included under arteriosclerosis The latter comprises three groups of lesions

1 *Medial calcification* with or without preceding degeneration or necrosis (Monckeberg s sclerosis[14]) This produces pipestem and beaded peripheral arteries but does not occlude the lumen or produce significant clinical symptoms The process usually involves medium sized muscular arteries such as the femoral artery These hardened arteries often show little or none of the lipoidal deposits and intimal thickening which characterize atherosclerosis

2 *Arteriolosclerosis (productive or hyperplastic arteriopathy)* which is characterized by endothelial hyperplasia thickening and hyalinization of the intima reduplication of the internal elastic lamina and hypertrophy of the media of the arterioles of the kidney and other viscera These lesions are associated usually with hypertension

3 *Atherosclerosis*[175] which affects chiefly the large and medium sized musculoelastic arteries (aorta coronary cerebral peripheral) It is characterized by intimal thickening due to lipoid atheroma fibrosis calcification necrosis and hemorrhage This is the type of arteriosclerosis which involves the coronary arteries and is responsible for coronary (atherosclerotic) heart disease Arteriosclerosis denoting hardening of the artery is a poor term for this form of disease because it is not the hardening but the intimal changes and thickening which lead to narrowing or occlusion Reference should be made also to the superficial yellowish lipoid deposits on the intima of the aorta and coronary arteries which appear commonly in the first decade of life and appear to be reversible in youth but may progress to atherosclerosis later in life Lande and Sperry [119] in a study of aortas from 89 individuals who had died of trauma or alcoholism without other disease found only 3 without macroscopic evidence of atheroma Early aortic atherosclerotic lesions were also found universally in 300 consecutive autopsies of subjects beyond the age of 7 [147]

Hyperplastic Arteriosclerosis This is a term applied by Moschcowitz[161] to vascular lesions characterized by hyperplasia of the intima and internal elastic layer and by hypertrophy of the media independent of atheromatous lesions Under this heading are included the changes seen in arterioles (classified above as arteriolosclerosis) and medium sized arteries and also those in the coronary and cerebral arteries In the latter the atheromatous deposits are regarded as a secondary facultative not primary lesion of arteriosclerosis

PATHOGENESIS OF ATHEROSCLEROSIS

Theories of atherosclerosis are concerned with two general questions viz (1) whether it is an irreversible immutable process of aging or one due to exogenous or endogenous factors which may be controlled and (2) whether the primary disease is an intrinsic abnormality in the vessel wall which then predisposes to secondary lipoid change either locally or by imbibition from the plasma or whether some primary metabolic change which alters the blood results secondarily in vascular lipoidosis and other degenerative changes The latter disagreement stems from uncertainty as to whether the initial lesion consists of degenerative alteration of the intimal collagen or ground substance [18 11] or of lipid containing foam cells arising in connection with lipid deposited from the blood stream [1]

AGING THEORY OF ATHEROSCLEROSIS

This theory supposes that atherosclerosis is an inevitable consequence of aging and therefore an irreversible process [151] In a general way the occurrence severity and extent of atherosclerosis including coronary atherosclerosis increase with age [197] On the

other hand coronary and other atherosclerosis is *frequently* minimal in very *old* people[17], in fact the absence of severe atherosclerosis of the coronary and cerebral vessels may be a prerequisite to the attainment of old age I have examined many hearts of subjects beyond the age of 70 who died at a home for the aged and often observed that the aorta and coronary arteries were remarkably free from significant atherosclerotic change

Another objection to the aging theory is the occurrence of advanced coronary atherosclerosis in youth e g in postmortem studies of young German recruits during World War I[113] and in young soldiers during World War II[69, 213, 41] and in the Korean War[44] Pulmonary atherosclerosis appears in young individuals dying of rheumatic mitral stenosis or of congenital cardiovascular abnormalities

Aging fails to explain the sharp difference in incidence and severity of atherosclerosis among men and women the reported difference in incidence in different countries, the variations in distribution among the different arteries and the high incidence in association with diabetes, xanthomatosis and myxedema

The atrophic and proliferative changes usually described as characteristic of aging differ from those seen in atherosclerosis The very term aging is a vague concept which involves many unknown elements, some or all of which may be subject to modification or control

For these various reasons the fatalistic assumption that atherosclerosis is an inevitable and inexorably progressive process should be *abandoned It is more probable that athero*sclerosis represents a disease process due to definite physical and chemical factors More fruitful results will be obtained if concentrated efforts are directed toward discovering and mastering these etiologic elements

METABOLIC THEORY OF ATHEROSCLEROSIS

One of the widely held theories of atherosclerosis relates its origin to a disturbance in lipid metabolism and more specifically in the metabolism of cholesterol The detailed evidence for this theory presented below, is based chiefly on the cholesterol content of human atherosclerotic lesions and on the development of hypercholesterolemia and atherosclerosis in many experimental animals following cholesterol feeding Many variants of this theory have been proposed Aschoff[11] believed that cholesterol and other lipids entered the arterial intima from the plasma by a process of imbibition and subsequently cholesterol ester and free cholesterol were deposited and retained in altered intimal tissue [21] The plasma is thought to pass into the intima by trans-endothelial imbibition and to filter through the artery from intima to adventitia where it is reabsorbed into the vasa vasorum The deposition of lipids or lipoproteins in the intima and the consequent development of atherosclerotic lesions may depend on the following factors (1) the plasma content of lipids or lipoproteins their concentration and physicochemical characteristics, (2) the arterial blood pressure and other mechanical factors which promote the filtration of lipids as lipoproteins from plasma through arterial wall, and (3) the structure and function of the arterial tissue, especially the intima which may determine whether lipoproteins are deposited and the responses of the intima to their degradation products Tissue permeability may also be a significant factor [illegible]

Anitschkow [3] among others, emphasized the primary importance of hypercholesterolemia in the deposition of cholesterol in the intima Leary[127] assumed that macrophages in the liver and other reticuloendothelial tissues accumulate cholesterol travel through the blood stream as cholesterol containing foam cells and penetrate the intima through spaces between the endothelial cells According to Leary the accumulation and disintegration of these lipophagic foam cells in the intima *result in soft lipoidal atheromata which are* characteristic of atherosclerosis According to Winternitz et al [illegible] the development of atherosclerosis depends on the presence of intimal capillaries which rupture and give rise to hemorrhages The extravasated blood is presumed to be the source of the cholesterol which leads ultimately to atheroma and necrotic intimal thickenings However, the existence of intimal capillaries in the normal vessel is uncertain, it is more probable that they arise secondarily after the atherosclerotic process has been initiated

Hueper[100] contended that colloidal imbalance in the plasma leads to the precipitation of the cholesterol as a film on the intima Consequently intimal nutrition by way of the vascular lumen is impaired This

results in subendothelial intimal anoxia injury and increased permeability of the endothelial cells and the infiltration and deposition of cholesterol from the serum This theory professes that the initial disturbance in atherosclerosis is one of instability of the dispersion of cholesterol in the blood due either to hypercholesterolemia or alteration in other substances in the blood which diminish the solubility of cholesterol This concept is based in part on the experimental production of atherosclerosis not only by cholesterol but also by polyvinyl alcohol methyl cellulose and similar macromolecular substances which impair the plasmatic colloidal equilibrium

EVIDENCE FOR METABOLIC THEORY

The metabolic theory is based chiefly on

(1) Pathologic and chemical studies of the atherosclerotic lesions

(2) Experimental production of atherosclerosis by feeding cholesterol

(3) Plasma lipids and lipoproteins

(4) Frequency and severity of atherosclerosis in association with diseases accompanied by hypercholesterolemia

(5) Purported rarity of atherosclerosis among people whose diet contains little or no animal fat (cholesterol)

Although the evidence is based on a vast array of studies and observations the reader is cautioned not to be carried away by the sheer number of these studies many of which are essentially repetitions which do not significantly amplify basic knowledge Much of the evidence is circumstantial and indirect One should constantly inquire whether the observations reported have a direct bearing on the pathogenesis of atherosclerosis *as it occurs in man* Two common assumptions which are made in interpreting experimental and other observations and which may or may not be valid are (1) that hypercholesterolemia or other alteration in plasma lipids is an index of the presence of significant atherosclerosis and that factors correcting hypercholesterolemia also retard or alleviate atherosclerosis and (2) that experimental atherosclerosis induced by cholesterol feeding alone or in combination with other factors may be regarded as essentially identical with human atherosclerosis and that factors which cause retard or reverse experimental atherosclerosis would also similarly influence human atherosclerosis A major difficulty in studies of human atherosclerosis is the inability to discover its presence until it is very advanced consequently one cannot assume that clinical disease may be employed as an accurate gauge of atherosclerosis Widespread atherosclerosis may be present when there are no clinical manifestations

1 Pathology and Chemistry of Atherosclerotic Lesions

Pathologic and chemical studies of atheromatous lesions have emphasized the presence of large amounts of lipids notably cholesterol esters and free cholesterol [337] The quantity exceeds that which can be explained by local degeneration [181] The concentrations of the various lipids correspond closely to their concentration in the plasma suggesting that they reach the intima by non selective infiltration or imbibition from the plasma [135, 97] In early lesions there is an increase in total lipids including free cholesterol and cholesterol esters phospholipids (lecithin and sphingomyelin) and neutral fat With the occurrence of degeneration and the development of advanced lesions most of the lipids diminish in concentration whereas cholesterol esters predominate Of special interest is the relatively high concentration of dihydrocholesterol (10 per cent of the cholesterol fraction) a metabolic product ordinarily secreted by the intestine and excreted in the feces since it is not reabsorbed The unstable lipids in the plasma are transported as lipoproteins chiefly beta lipoprotein After this is filtered from plasma to the vascular intima the filtered lipoprotein breaks down leaving the lipid to which intimal tissues react as if it were an inert foreign body Most of the soluble amino acids fatty acids and lipoproteins passing through the arterial wall are resorbed by the adventitial capillaries and lymph Pathologic observations strongly suggest that the baneful consequences of atherosclerosis are largely due to the deposits of cholesterol esters in the intima and the secondary reactions to its presence (p 430)

2 Experimental Atherosclerosis

Atheromatous vascular lesions resembling those of human atherosclerosis have been produced experimentally in rabbits guinea pigs hamsters pigs and chickens by feeding large quantities of cholesterol or animal fat [10 ... 115] A pronounced hypercholesterolemia precedes the development of the atheromatous lesions

and is presumed to be the primary disturbance leading to intimal cholesterol deposition The experimental production of hyperlipemia and early atherosclerosis in rabbits by a high vegetable fat diet has also been reported [redacted]

Many objections have been raised to the validity of applying these experimental observations to the explanation of human atherosclerosis[44, 173] The rabbit is an herbivorous animal man is omnivorous Attempts to produce atherosclerosis by cholesterol feeding in a variety of carnivorous or omnivorous animals have been very difficult and the distribution of atherosclerotic lesions in herbivorous animals differs from that in human atherosclerosis The quantity of cholesterol fed to rabbits [redacted] proportionately far in excess of that usually taken by man and the resulting hypercholesterolemia has no counterpart in the majority of cases of human atherosclerosis Atherosclerosis in man appears to be related more to the arterial reactions, degeneration and repair than to the level of serum cholesterol which is the determinant in the rabbit The lesions of experimental atherosclerosis in the rabbit are chiefly in the reticuloendothelial tissues and parenchymal organs and not as prominent in the coronary or cerebral arteries as in human atherosclerosis However, some of these objections to any analogy between experimental atherosclerosis in rabbits and human atherosclerosis appear to have been overcome by the experimental production of a generalized atherosclerosis in the omnivorous dog, by means of daily feeding of cholesterol after modification of thyroid function by thiouracil[204] or radioiodine administration or after production of renal hypertension Atheromatosis produced in chickens by subcutaneous implantation of diethylstilbestrol [7] and in the rhesus monkey by maintaining pyridoxine deficiency,[180] or by feeding cholesterol with diets low in sulfur containing amino acids[123] also resembles human atherosclerosis particularly in that the cerebral and coronary arteries are involved On the other hand, atheromatosis has not been produced in rats by feeding diets which are atherogenic in other specie But atherosclerotic lesions have been produced in the rat by feeding cholesterol and methyl thiouracil after having induced renal hypertension It will be noted that in many species cholesterol feeding is effective in producing atherosclerosis only when thyroid function is simultaneously depressed, renal hypertension is established or the cholesterol is administered in diets deficient in certain respects (pyridoxine sulfur amino acids)

3 Plasma Lipids and Lipoproteins and Atherosclerosis

The relation of experimental atherosclerosis to hypercholesterolemia has stimulated extensive investigations of blood lipids in humans and their possible connection with human atherosclerosis

The *blood lipids* include chiefly

(a) Neutral fats—esters of fatty acids and glycerol

(b) Phospholipids (phosphatides)—fats which contain in addition phosphoric acid and nitrogenous groups such as choline The phospholipids include chiefly lecithin but also the cephalins and sphingomyelin

(c) Cholesterol—hydrogenated phenanthrene derivatives The plasma cholesterol is a steroid with an iso-octyl chain at carbon 17 About 70 per cent of it is normally in the ester form as a result of combination with fatty acids mostly unsaturated, attached to carbon 3

The total plasma lipids amount to about 700 mg per 100 cc of which total cholesterol forms about 33 per cent and the phospholipids about 35 per cent, the remainder is neutral fat

All of the lipids in the blood are transported in combination with proteins, as lipoprotein complexes (p 422) which serve to maintain the lipids in colloidal solution in the blood

Plasma Cholesterol and Atherosclerosis Efforts to discover hypercholesterolemia in humans with coronary or other forms of vascular atherosclerosis have yielded contradictory results[6] [redacted] Lande and Sperry[10] found that determinations of plasma cholesterol after accidental death revealed no difference between individuals with extensive atherosclerosis and those without such vascular disease On the other hand, Davis et al[43] observed higher values for blood cholesterol and other lipids in a group of patients with angina pectoris presumably due to coronary atherosclerosis than in a group of control patients But there was a wide range of values and considerable overlapping of individual values in both groups in these and other studies[14] Barker[1] likewise found a

higher mean level of plasma lipids in cases of arteriosclerosis obliterans than in normal controls but the range in both groups was essentially similar Like the incidence of atherosclerosis the concentration of serum cholesterol tends to rise with age but not in all persons nor in peoples of all countries [115]

Of possibly greater significance are the findings of Steiner and Domanski[203] who studied the cholesterol levels of 15 patients with coronary atherosclerosis and of 15 normal subjects at frequent intervals for periods up to two years In the former group they observed a distinctly higher average serum cholesterol but especially noted that it was inconstant and fluctuated widely while the values in normal subjects remained relatively constant Since atherosclerosis requires a long period of development isolated determinations of the blood cholesterol may not reflect intermittent variations Since the normal content of serum cholesterol is close to its saturation point deposition of cholesterol may follow slight elevations above normal levels The interpretation of reported values for serum cholesterol is obscured by technical difficulties in the methods for cholesterol determination and by uncertainty as to the range of normal Furthermore since atherosclerosis is widespread at a relatively early age whereas clinical manifestations appear relatively late many of the individuals serving as normal controls who have hypercholesterolemia may quite possibly have clinically latent atherosclerosis

Moreton proposed the theory that the cumulative effect of numerous fatty meals produces transient showers of large lipid particles (chylomicrons) which are deposited in the arterial intima and may lead to atherosclerosis [147] The neutral fats and fatty acids are more readily removed and resorbed by macrophages and tissue enzymes than the large lipid particles which accumulate to form atheroma

The Plasma Cholesterol Phospholipid Ratio and Atherosclerosis In recent years emphasis on total serum cholesterol as an index of atherosclerosis has diminished somewhat and attention has been shifted to (1) the plasma cholesterol phospholipid ratio (2) the concentration of plasma alpha and beta lipoproteins or the percentage of cholesterol in alpha and beta lipoproteins and (3) the concentration of lipoprotein molecules of specific size in the plasma as disclosed by the analytical ultracentrifuge It should be emphasized that the abnormal lipid or lipoprotein values and relationships are *not* present in all atherosclerotic individuals and that there is considerable overlapping between normal and atherosclerotic individuals

Ahrens and Kunkel[3] suggested that the ratio of cholesterol to phospholipid concentration was an index of the stability of lipid solutions in the blood and that this cholesterol phospholipid ratio not the cholesterol concentration alone was a determining factor in the development of atherosclerosis Cholesterol is insoluble in aqueous solution but phospholipids tend to keep it in solution in the blood Elevation of the cholesterol phospholipid ratio may predispose to the precipitation of cholesterol in the arterial intima

In normal rabbits the cholesterol phospholipid ratio is less than 1 in rabbits with atherosclerosis induced by cholesterol feeding the ratio is greater than 1 [184] In species such as the dog in which significant atherosclerosis does not appear spontaneously and is difficult to produce experimentally the proportion of cholesterol to phospholipid is much lower than in man But when atherosclerosis is produced experimentally in the dog by combining thiouracil with cholesterol feeding the cholesterol phospholipid ratio rises considerably [40] The inhibition of experimental atherosclerosis in cholesterol fed rabbits by the production of alloxan diabetes was associated with a much greater elevation in serum phospholipids than in serum cholesterol and therefore with a reduction in the cholesterol phospholipid ratio [17, 41, 27] A similar reduction in the cholesterol phospholipid ratio occurred when atherosclerosis was inhibited in the cholesterol fed rabbit by cortisone [75] or in the cholesterol fed chick by stilbestrol [170]

The plasma cholesterol phospholipid ratio has also been correlated with human atherosclerosis Gertler Garn and Lerman[80] found the average serum cholesterol phospholipid ratio significantly higher in patients who had survived a coronary artery occlusion than in normal young men of comparable age Steiner and associates [94] found that the serum cholesterol and serum phospholipid but also the cholesterol phospholipid ratio were increased in most of 82 patients with clinical coronary atherosclerosis However in many

persons with coronary occlusion the cholesterol phospholipid ratio is in the normal range, and Wilkinson [illegible] found that the cholesterol phospholipid ratio was not significantly different in patients with clinical atherosclerosis from that in patients in a large miscellaneous group Furthermore he observed that the cholesterol phospholipid ratio was dependent exclusively on the cholesterol level unless there was hepatic insufficiency

The hypothesis that atherosclerosis is related to the physical state of the blood lipids or lipoproteins has led to the study of other agents which like the *phospholipids may influence* lipid solubility The injection of surface-active agents, such as the detergents Tween 80 and Triton A 20 into cholesterol fed rabbits not only caused a marked sustained elevation in serum phospholipid but also greatly inhibited the development of atherosclerosis[166, 107] Metal binding agents such as the chelator EDTA and hydralazine were found to cause a prompt fall in plasma cholesterol in man[88]

There has been a renewal of interest in the observation of Hahn[85] that an injection of heparin cleared the postprandial lipemic serum of the dog but was ineffective in vitro Anderson and Fawcett[7] showed that the injection of heparin led to the formation of another substance surface active heparin phospholipid complex, which was actually responsible for the clearing Anfinsen et al [8] found the clearing factor to be a protein complex containing no free heparin but liberating it on boiling The protein complex was inactivated by protamine

Heparin was reported to retard the development of atherosclerosis in cholesterol-fed rabbits and to diminish the concentration of the atherogenic beta lipoproteins[154] and the S_f 10–50 lipoprotein aggregates[79] But these findings were not confirmed by Herbst et al[92] It was found that alimentary lipemia was cleared by an injection of a 3 mg dose of heparin more readily in normal individuals than in atherosclerotic patients The formation of heparin has been related to the mast cells which are dispersed around blood vessels[36] Mast cells were found to be abundant *in animal species such as the rat*, in which it is difficult to produce atherosclerosis, and relatively sparse in the rabbit in which atherosclerosis is readily produced[36] A lower count of mast cells was found in elderly females than in young female adults, and in atherosclerotic individuals than in non atherosclerotic individuals[27])

Sulfated alginic acid, a synthetic analogue of heparin, was reported to inhibit the hypercholesterolemia and atherosclerosis usually caused by cholesterol feeding in rabbits [illegible]

Plasma Lipoproteins and Atherosclerosis Although the various plasma lipids are identified individually and their concentrations determined by chemical means, they do not circulate as such in the blood plasma but are transported in combination with proteins as *lipoproteins* The *standard methods for* determining plasma lipids utilize organic solvents which precipitate the protein moieties and extract the lipids free of protein Lipoproteins are not well defined chemical entities of uniform stoichiometric composition They are segregated and identified directly or indirectly by (1) salt fractionation of plasma proteins (2) electrophoresis of blood plasma, (3) alcohol fractionation of plasma proteins, or (4) flotation in the ultracentrifuge

(1) *Plasma albumin can be separated from* the globulins by precipitation of the latter with 50 per cent saturated ammonium sulfate or 22 per cent concentration of sodium sulfate The globulins are separated into euglobulin, pseudoglobulin I and pseudoglobulin II by precipitation with various concentrations of sodium sulfate (13 5, 17 5 and 21 5 per cent, respectively) The alpha and beta lipoproteins are associated with both pseudoglobulin I and II

(2) *Electrophoresis separates* the various plasma proteins, which differ in the magnitude of their electrical charge by differences in their speed of migration in an electrical field *In this manner*, albumin alpha globulins, beta globulin and gamma globulin are differentiated The alpha and beta lipoproteins are the lipoproteins which migrate with the same speed as the alpha and beta globulins respectively More specifically they are termed $alpha_1$ and $beta_1$ lipoproteins [illegible] Recently, the simple, inexpensive rapid technique of paper electrophoresis has been used whereby the various serum proteins migrate in an electrical field set up across a strip of filter paper saturated with buffer[101] A column of starch has been similarly employed in the separation of plasma proteins by zone electrophoresis[115]

(3) *The Cohn method of fractionation of*

plasma utilizes the variable solubility of various protein fractions in different concentrations of ethyl alcohol (14.25 to 19 per cent) at low temperatures (minus 5° C.) at varying pH, ionic strength and protein concentration. Cohn's fraction V contains plasma albumin, fraction IV contains the alpha$_1$ globulin (and alpha$_1$ lipoprotein), fraction III, especially III, contains the beta$_1$ globulin (and beta$_1$ lipoprotein).

The plasma cholesterol and the phospholipids are carried as alpha and beta lipoproteins. But only about 25 to 30 per cent of the total cholesterol in humans forms part of alpha lipoprotein, whereas 70 to 75 per cent of the plasma cholesterol is found in the beta lipoprotein fraction.[160] By contrast, in species relatively resistant to atherosclerosis the percentage of cholesterol is high in the alpha lipoprotein and low in the beta lipoprotein fraction. The percentage of total cholesterol in the alpha lipoprotein is highest in young and normal humans, diminishes with age and is lowest in patients with disease predisposing to atherosclerosis and in those who have survived a myocardial infarction.[11]

The ratio of cholesterol to phospholipids in plasma alpha lipoproteins averages 0.5, whereas the cholesterol phospholipid ratio in the fraction containing the beta lipoprotein averages more than 1.0.[illegible, 160] Thus if an elevated plasma cholesterol concentration or a high cholesterol phospholipid ratio contributes to the development of atherosclerosis, then the latter is also favored by elevated concentrations of beta lipoprotein with its high cholesterol and high cholesterol phospholipid ratios. The ratio of beta to alpha lipoprotein as well as the percentage of cholesterol in the beta lipoprotein fraction increases with age and is increased in patients who have recovered from a coronary thrombosis. These changes in lipoprotein concentration were found to correlate more closely with clinical coronary atherosclerosis than an elevation in plasma cholesterol or the cholesterol phospholipid ratio. The correlation of atherosclerosis with relative and absolute increase in the beta lipoprotein fraction may be related to lesser stability of the beta lipoprotein fraction than the alpha and consequently greater probability of dissociation and deposition in the arterial intima.

(4) The plasma lipoproteins may also be differentiated by the ultracentrifuge in which the strong gravitational force floats the large protein molecules to the surface at velocities related to their molecular weight and the specific gravity of the solution. The density of the plasma sample is first increased to 1.063 at 26° C. by the addition of sodium chloride (or to 1.21 by the addition of potassium bromide). The lipoproteins which are of lower density than ordinary proteins are then readily made to migrate (float) toward the axis of rotation of the ultracentrifuge. By the use of optical scanning devices and photography, the migrating boundaries and quantities of the individual plasma proteins of different molecular weights can be observed and photographed. The lipoproteins are designated in terms of S_f units (Svedberg flotation units), a unit denoting a migration rate of 10^{-13} cm. per second per dyne per gm. A lipoprotein which migrates (floats up) at ten times the above rate of speed is identified as a lipoprotein of the S_f 10 class.

By studying the flotation of plasma lipoproteins in the ultracentrifuge, Gofman and associates[73, 104] found an entire series or "spectrum" of lipoproteins varying in flotation rate from S_f [illegible] to S_f 4000. They found evidence that patients with clinical coronary atherosclerosis have a high concentration of S_f 12–20 lipoprotein much more often than normal individuals. Later a similar correlation was made between atherosclerosis and lipoproteins of the S_f 20–200 classes. The S_f 12–20 lipoproteins and to a lesser degree those of the S_f 20–200 class were regarded as atherogenic since their concentration was found to be greater in males than females, increased with age and in those with a history of coronary occlusion, and rose with the experimental production of atherosclerosis in rabbits. The correlation between S_f 12–20 and S_f 20–200 lipoprotein levels and atherosclerosis was reported to be two to four times as great as that of serum cholesterol levels and atherosclerosis,[illegible, 104] although this has been refuted by Keys.[109] Low cholesterol, low fat diets and the injection of heparin, which were thought to influence atherosclerosis favorably, also altered the lipoprotein pattern toward normal. Gofman and associates[73] have actually claimed the ability to assess the degree of probability that an individual had experienced or was apt to experience sig

nificant clinical coronary disease Most of these claims are unsubstantiated at the present time some studies testing these claims have not yet been reported There is considerable overlapping of the so called atherogenic lipoprotein classes in normal and atherosclerotic individuals and considerable error in attempting to correlate the concentration of various S_f classes of lipoproteins with clinical atherosclerosis

The relationship of lipoproteins to atherosclerosis is considered chiefly from the view point of its cholesterol and other lipid content and distribution The possibility must also be considered if such a lipoprotein atherosclerosis relationship exists that it is the protein moiety which accounts for the disturbance leading to lipid deposition and atherosclerosis It is of interest that atherogenesis in cholesterol fed monkeys is augmented by a diet deficient in sulfur containing amino acids

Cholesterol Metabolism and Atherosclerosis [196, 187, 74] With growing interest in the possible relation of cholesterol and hypercholesterolemia to atherosclerosis and with the availability of radioisotopic techniques, investigations of cholesterol metabolism have assumed increasing importance These studies are concerned with the interrelationship of dietary intake (exogenous) cholesterol the synthesis of (endogenous) cholesterol degradation of cholesterol excretion of cholesterol and the metabolism of cholesterol within different organs and tissues notably the aorta

The dietary intake of cholesterol by the human adult is about 200 to 500 mg daily and varies particularly with the intake of animal fats This compares with the ability to synthesize 1 5 to 2 0 gm daily from various sources [77] Cholesterol absorption is aided by ingested fats and especially by secreted bile The cholesterol is chiefly absorbed by the lymphatics and enters the blood stream where it is transported in combination with alpha and beta globulins as alpha and beta lipoproteins According to Friedman and Byers [81] endogenous and dietary (exogenous) cholesterol exist in plasma in different states and are handled differently The absorption of cholesterol from the intestine includes not only dietary cholesterol but also 0 5 to 1 5 gm of cholesterol excreted by the liver in bile Cholesterol absorption may be impaired by low fat diets, sitosterols and other agents

The liver is the major organ concerned with cholesterol which it can synthesize store and destroy [77, 81] By these processes it largely determines and controls the level of serum cholesterol The latter is maintained fairly constant by some homeostatic regulation of the dynamic equilibrium between the absorption and synthesis of cholesterol on the one hand and the metabolism and excretion on the other [76] Cholesterol esters (i e , cholesterol esterified with fatty acids) are formed essentially in the liver with the aid of enzymes and constitute 70 per cent of total plasma cholesterol However studies with C^{14} labeled cholesterol have shown that most tissues beside the liver can synthesize cholesterol, especially the adrenal gland [199, 77, 213]

Cholesterol is synthesized in the human even in the absence of dietary cholesterol [21, 81] from acetate acetoacetate pyruvate butyrate and stearate which in turn are derived from dietary carbohydrates proteins and fats The acetate fragments are esterified with the thiol group of coenzyme A to form acetyl coenzyme A, the active acetic acid Coenzyme A may be concerned with both the synthesis and degradation of cholesterol The exact steps in the synthesis of acetate into cholesterol are uncertain but studies with radioactive isotopes indicate that the unsaturated hydrocarbon squalene is an intermediate [181, 187] When the dietary intake of cholesterol is increased endogenous synthesis is inhibited or when the former is diminished cholesterol synthesis is increased [81] Consequently it is difficult to lower serum cholesterol for sustained periods by limiting cholesterol intake There is evidence that in the rat cholesterol synthesis is inhibited by estrogens and augmented by corticosteroids

Cholesterol is oxidized in the body to carbon dioxide by many tissues but most actively by the liver Some of the cholesterol is converted into steroid hormones and most of it into bile acids which are excreted in the bile Cholesterol may be disintegrated to dihydrocholesterol by direct reduction or to dihydrocholesterol or coprosterol through the intermediate cholestenone Thirty one per cent of the iso-octyl side-chain carbon is eliminated as carbon dioxide in the expired air [76] whereas none of the ring carbon appears as carbon dioxide, it is recovered in the saponifiable fraction of the fecal steroids Cholesterol itself and its products, dihydro

cholesterol and coprosterol, which are poorly absorbed are excreted in the feces

There are considerable data indicating that blood vessels participate actively in metabolism and that the aortas of various species are capable of synthesizing cholesterol from acetate and of oxidizing it to carbon dioxide These observations have raised the question whether and to what extent atherosclerosis i e the deposition of cholesterol in arteries is secondary to faulty arterial metabolism

Studies of cholesterol metabolism have not yet disclosed whether or not atherosclerosis is fundamentally an inborn or acquired metabolic disturbance with respect to this substance Such a metabolic disturbance could produce atherosclerosis if (1) there was excessive cholesterol synthesis beyond the quantity which could be catabolized or excreted (2) there was excessive absorption of *cholesterol or diminished excretion, (3) there* were abnormalities in its combination as lipoproteins or in its transport in the blood stream resulting in impaired stability of cholesterol colloids and consequent deposition in the arterial walls or (4) there was interference with the transit of cholesterol through the arterial wall due to mechanical factors or to impairment of vessel metabolism The last possibility would suggest that primary abnormalities in the structure or function of vessels are more important than disturbances in cholesterol metabolism in the development of atherosclerosis

4 Atherosclerosis in Diseases with Hypercholesterolemia

The frequency severity and precocity of coronary atherosclerosis in diseases associated with hypercholesterolemia add considerable support to the cholesterol theory of atherosclerosis In the cases of *familial xanthomatosis with hypercholesterolemia* there is an unusually high incidence of angina pectoris coronary occlusion and death at an early age because of severe coronary atherosclerosis Genetic analysis is said to support the concept that familial xanthomatosis is a disturbance in *cholesterol or lipid metabolism which is* inherited as an incomplete dominant mendelian trait Xanthomatous lesions occur only in patients who are homozygous i e carry two abnormal genes with respect to the cholesterol disturbance [■ 333] Heterozygous individuals with only one abnormal gene, have only hypercholesterolemia or less severe manifestations of xanthomatosis The theory has been proposed that coronary atherosclerosis likewise represents a related inborn error of lipid or cholesterol metabolism, manifested by an elevated serum cholesterol[2] This concept is based largely on the high incidence of hypercholesterolemia in patients with coronary atherosclerosis below the age of 50 but also in the finding of hypercholesterolemia in one third to one half of the siblings of such patients[2] However the relationships are statistical not universal and the analogy to familial xanthomatosis may be quite superficial and fortuitous The arbitrary choice of normal values for serum cholesterol the effect of diet race and possible other factors in the level of serum cholesterol, the overlapping of normal and elevated serum cholesterol levels in presumably normal persons and in those with coronary atherosclerosis *as well as the unproven assumption* that hypercholesterolemia causes and ■ an index of human atherosclerosis are among the difficulties or objections to acceptance of the above theory that coronary atherosclerosis is closely related to or is a mild form of familial hypercholesterolemia

Essential hyperlipemia is likewise thought to be frequently associated with premature atherosclerosis[194] but if atherosclerosis is present hypercholesterolemia is usually also associated

The etiologic relationship of diabetes to premature and advanced atherosclerosis is discussed elsewhere (p 1034) The frequency of advanced atherosclerosis in youthful diabetics and *atherosclerotic* coronary *thrombosis in* diabetic women in contrast with its infrequency among nondiabetic women are unexplained observations which are among the most important clues we possess to the cause of atherosclerosis Rabinowitch[77] and others have associated the high incidence of atherosclerosis among diabetics with hypercholesterolemia in the more severe and poorly controlled cases But Man and Peters[131] found that atherosclerosis with or without hyper*tension* occurred *in 79* diabetic patients whether the blood cholesterol was normal or abnormal

Premature atherosclerosis in diabetes was formerly attributed to the high fat diets in the pre-insulin era But there has been no demonstrable reduction in the incidence or severity of atherosclerotic complications de

spite the use of high carbohydrate diets and better control of fat and carbohydrate metabolism with insulin In fact by prolonging the lives of diabetic patients, such measures permit more of them to survive long enough to become victims of atherosclerosis (p 1031) *Nevertheless evidence has been* presented that among young diabetics who had survived twenty years of diabetes 74 per cent of those incapacitated by atherosclerosis of the heart eyes or kidneys had repeatedly experienced coma, while only 17 per cent of those without atherosclerosis had experienced coma [5] The specific metabolic or endocrine factor in diabetes which predisposes to atherosclerosis remains uncertain

Severe coronary atherosclerosis is said to be a common finding in cases of myxedema, which is characteristically associated with hypercholesterolemia [5] (p 1017)

5 Relation of Atherosclerosis to Diet

Two types of studies have related the dietary intake of cholesterol to the development of atherosclerosis (1) The quantity of cholesterol intake has been correlated with the level of serum cholesterol or lipoproteins, which is presumed to be an index of atherogenesis (2) *The incidence of morbidity and* mortality from atherosclerosis has been correlated with the cholesterol intake by various ethnic groups in different geographic regions or under different economic political circumstances

Cholesterol Intake and Serum Cholesterol This problem is *complicated by a frequent* failure to distinguish between high cholesterol and high fat intake since foods rich in fats are usually but not invariably high in cholesterol content Cholesterol is found in fats of animal origin but not in vegetable fats In man cholesterol feeding produces little or no change in plasma cholesterol and there is little correlation between serum cholesterol and cholesterol *in the diet over a wide range of* intake [11, 234, 69] Only with extreme reductions in cholesterol and fat intake (20 gm of fat and virtually no cholesterol) is the serum cholesterol reduced [20, 135] On the other hand, when vegetable fat containing no cholesterol was added to such a low cholesterol, low fat diet the previously lowered plasma cholesterol returned to its original higher level [85, 136] The conflicting *observations of Kinsell et* al [116] *regarding the influence of vegetable fat* may be related to the type of vegetable fat employed (p 437) Only highly unsaturated *fats may produce a significant reduction in* serum cholesterol According to Jones et al [102] the so-called atherogenic Sf12–20 lipoproteins diminish markedly in individuals on a low fat and low cholesterol diet

According to Keys et al, *the serum cho*lesterol level and the cholesterol content of the diet in Minnesota are unrelated [11] When the cholesterol intake of middle-aged men was reduced by 50 per cent or more for a year, the serum cholesterol levels remained unaltered On the other hand there was a rapid decline *in the serum cholesterol when these subjects* were placed on cholesterol free, fat free diets Observations of the Eskimos in the Aleutian Islands also indicate that the serum cholesterol is not significantly influenced by cholesterol in the diet Although these individuals subsist on a fairly uniform high *protein fish diet which contains little cho*lesterol their serum cholesterol levels did not differ from that of adult Americans and in 4 of 81 there was hypercholesterolemia [83] Garn and Gertler[83] concluded that endogenous mechanisms and not dietary cholesterol intake were responsible for the level of serum cholesterol *It now appears that the dietary* intake of fat and not of cholesterol per se exerts a strong influence on serum cholesterol Populations habitually subsisting on low fat diets as in Italy, Spain and certain parts of Africa, have a relatively low plasma cholesterol, and the plasma cholesterol level *does not rise and may fall with age* in contrast with the findings in this and other countries in which the intake of fat is high [115] [116] In a recent study the serum cholesterol and beta lipoprotein concentrations of rural Central American subjects who take a vegetarian diet very low in fat were compared with the corresponding serum constituents in urban Guatemalan and North *American subjects on a relatively* liberal fat diet [134] The serum cholesterol was found to be significantly lower in the group on a low fat diet but the lipoprotein levels in the three groups were variable and not significantly different

Cholesterol Intake and Atherosclerosis The occurrence of atherosclerosis in man has also been related to the dietary intake of fat, *rather than of cholesterol* Studies of the dietary intake in various countries and climates *have been interpreted to indicate a higher*

rate of atherosclerosis among people consuming a diet high in fat than among those on a low fat diet[208, 183] Snapper[186] commented on the rarity of advanced atherosclerosis among the northern Chinese who subsist on cereals and omit animal fats A similar paucity of atherosclerosis among the Okinawans and Costa Ricans was attributed to their low intake of cholesterol-containing food

In a Cape Town province the Bantus obtain 16 per cent of their calories from fat the Negroes 25 per cent and the local Europeans like persons in the United States obtain 40 per cent of their calories from fat[114] Severe atherosclerosis and myocardial infarction is very rare among the Bantus fairly frequent among the Cape Province Negroes and very common among the Europeans Within each of the groups the serum cholesterol was found to be directly related to dietary fat intake Aschoff[11] reported a sharp diminution in atherosclerosis in Germany following World War I when the populace was ingesting a particularly low fat diet Similarly in Norway and other European countries in World War II there was a sharp reduction in morbidity and mortality from clinical atherosclerosis including coronary heart disease presumably due to the great reduction in fat and cholesterol in the diet[44, 330, 209a] The incidence of clinical atherosclerosis rose rapidly following restoration of a more normal food intake Similarly when the Jews from Yemen where they subsisted on a low fat diet and experienced little coronary heart disease emigrated to Israel where their diet became rich in fats their serum cholesterol rose and the incidence of coronary heart disease increased significantly[159a] These reports on the relation of diet and atherosclerosis are suggestive but suffer from an inadequacy of statistical data and a multiplicity of factors besides dietary intake which may be concerned

A low serum cholesterol and a low incidence of coronary heart disease in a given racial group are not invariably associated with a low fat diet Thus it was found that coronary heart disease is rare among the Navajo Indians Nevertheless despite the relatively high incidence of coronary heart disease and the higher serum cholesterol levels among control subjects in Cleveland the dietary habits of the Navajo Indians did not differ from those of the control subjects[184] These observations were interpreted as suggesting that heredity, rather than the diet was the most likely explanation for the low levels of serum cholesterol and the low incidence of coronary heart disease among Navajo Indians

ENDOCRINE FACTORS

Gonadal Hormones

One of the most striking features of coronary atherosclerosis is the pronounced predilection for the male sex especially in the absence of diabetes or hypertension in the female Any satisfactory theory of atherosclerosis should explain this difference The purported difference in thickness of the arterial intima in the two sexes has not been substantiated The possible relationship to differences in tobacco intake has not been adequately explored The possible relationship of the sex hormones to atherosclerosis is indicated by studies of the serum lipoproteins in the two sexes by experimental observations on the effect of estrogenic hormones and by other pertinent findings

It has been found that normal young women, in whom coronary occlusion is rare have a relatively smaller amount of beta lipoprotein and a higher concentration of alpha lipoprotein than normal young men but this sex difference is no longer apparent after the menopause[166, 184] Correspondingly the atherogenic lipoproteins of the Sf10–100 classes in the ultracentrifuge are likewise found in lower concentration in young women than in young men[10] The sex differences with respect to serum lipoproteins are absent when women suffer from atherogenic diseases such as diabetes nephrosis or familial hypercholesterolemia (These observations suggested that estrogenic hormones might influence the development of atherosclerosis by their effect on the distribution or nature of the plasma lipoproteins)

Postmortem observations have been interpreted as linking atherosclerosis to gonadal influences The incidence and severity of coronary atherosclerosis in bilaterally oophorectomized women is greater than in control females and approximates that in men of the same age range Conversely the incidence and severity of atherosclerosis was much less in men treated with estrogens for carcinoma of the prostate than in control series[181]

The administration of estrogens inhibits the development of cholesterol induced coronary

atherosclerosis in cockerels[105] Estrogens were also capable of *reversing* coronary atherosclerosis induced experimentally by cholesterol feeding[170] Estrogens administered to premenopausal and postmenopausal women caused a reduction in both the serum cholesterol and the serum cholesterol phospholipid ratio[53] Gertler[65] observed that the administration of 500 mg of stilbestrol to 25 men following bilateral orchidectomy for carcinoma of the prostate resulted in an increase in serum phospholipid without change in the serum cholesterol level Other observers[157, 205] reported a significant fall in serum cholesterol or cholesterol ester and in the cholesterol phospholipid ratio without change in or with elevation of the phospholipid level in patients with a previous myocardial infarction who received 0 25 mg to 1 mg of ethinyl estradiol (Estinyl) daily

Extensive studies of the effect of estrogens on serum lipids were made by Barr and associates[15, 188] They administered 1 mg daily of ethinyl estradiol or its equivalent, as Premarin or other estrogen to survivors of acute myocardial infarction The abnormal elevation of the beta lipoprotein fraction and the increased percentage of total cholesterol in this fraction were largely or totally corrected following estrogen administration At the same time there was a reduction in serum cholesterol and an increase in serum phospholipid, and consequently a fall in the cholesterol phospholipid ratio from a mean of 1 05 to 0 72 The effects were maximal in 8 weeks When androgens were administered simultaneously in an effort to neutralize the unpleasant side effects of the estrogens, the effects of the latter in plasma lipids were diminished or obliterated This is in contrast to the findings of Stamler et al[201] that the combination of estrogens and androgens administered to the cholesterol fed chick prevented the development of atherosclerosis

Other Hormones

Thyroid relationships to atherosclerosis have been noted Depression of thyroid function by thiouracil enabled the production of atherosclerosis by cholesterol feeding in the previously resistant dog[208] Thyroid administration inhibits experimental atherosclerosis in the cholesterol fed rabbit[217] or chick[203] Large doses of thyroid (10 grains daily), administered to schizophrenic patients, uniformly lowered serum cholesterol and the "atherogenic" lipoproteins[209] Myxedema is associated with hypercholesterolemia which is thought to predispose to atherosclerosis In hyperthyroidism there is increased intestinal excretion of cholesterol as well as somewhat increased synthesis of cholesterol by the liver The plasma cholesterol is slightly diminished in hyperthyroidism, perhaps because the increased intestinal excretion exceeds the augmented synthesis of cholesterol[6]

Adrenal Cortex The adrenal cortex is concerned with the regulation of cholesterol and other lipid metabolism[91, 4] and may thus play a part in the development of atherosclerosis Cushing's disease due to excessive adrenocortical hormones, is frequently associated with hypercholesterolemia The administration of cortisone has been followed by hyperlipemia and hypercholesterolemia An increased deposition of lipids in both the intima and media of the aorta has been noted in children who had received cortisone or corticotropin But neither cortisone nor corticotropin has favored experimental cholesterol atherogenesis According to Gordon et al[73] and Stumpf and Wilens,[11] experimental atherosclerosis in rabbits is impeded by the simultaneous administration of cortisone with cholesterol A hormonal influence may also be involved in the association of atherosclerosis with diabetes insofar as the latter is related to disturbances in the anterior pituitary, adrenal cortex or pancreatic islets

MECHANICAL FACTORS IN ATHEROSCLEROSIS INTRAVASCULAR PRESSURE AND HYPERTENSION

The localization of atherosclerosis in varying degree in different vascular beds is of great interest Atherosclerosis may be most intense in either the coronary cerebral or peripheral arteries It is not clear why atherosclerosis should involve the vessels in one and not the other area or should involve them to different degrees, when all the vessels are bathed by blood of the same lipid concentrations unless mechanical intravascular factors or differences in vascular structure and function are concerned Similarly, hypercholesterolemia does not cause atherosclerosis of veins This may be attributed to the lower pressure in veins relative to that in arteries But even when phlebosclerosis is associated with high venous pressure the sclerosis consists of hyperplasia and hypertrophy without atheromatous (lip

oidal) intimal deposits. This suggests the importance of the vessel structure or function as well as the chemical composition of the blood and the intravascular pressure in the development of atherosclerosis.

(Many types of mechanical strain or injury have been credited as initiating accessory or aggravating causes of atherosclerosis.[115] Intimal damage is said to result from the constant wear and tear on the blood vessels due to the impact of the intravascular blood pressure. Purported hereditary atherosclerosis is viewed as the consequence of an inherited inferiority of the vascular structure in its ability to withstand these strains. The localization of severe atherosclerotic lesions at the bifurcation of arteries and the mouths of branches is said to be due to the greater impact of the blood at these sites. The severity of atherosclerosis at the site of bifurcation of the left coronary artery into anterior descending and circumflex branches may be related to the size of the angle formed by these branches. Coronary atherosclerosis affects the main epicardial vessels, not the perpendicular penetrating myocardial branches. Greater mechanical strain may account also for the predilection of atherosclerosis for the posterior wall of the aorta where there is greater vascular fixation[179] and for the vessels of the lower extremities as compared to the upper. Such forces as tension, vibration, shearing between intima and media and intimal herniation have been postulated as representing irritant stimuli which damage intimal tissue and provoke proliferation, thickening and secondary atheroma formation.[17, 118] Mechanical intimal injury may be considered as a primary change which predisposes to the deposition of lipid. Or the lipid deposits may be primary while the intimal injury is an accessory factor which is important in determining the localization and intensity of the deposits.)

According to Moschcowitz[151] arteriosclerosis may result from the mechanical effects of the normal systemic intravascular pressure acting over a long period of time. Hypertension representing an elevation of the normal intravascular pressure accelerates and intensifies the arteriosclerotic process. Even when there is hypertension and arteriosclerosis in the greater circulation, arteriosclerosis is usually absent in the pulmonary vessels because, according to Moschcowitz, the pulmonary arterial pressure is only about one sixth of the normal systemic blood pressure. On the other hand pulmonary arteriosclerosis occurs commonly in the presence of long standing mitral stenosis or pulmonary conditions which produce hypertension of the pulmonary circulation.[151] The occurrence of phlebosclerosis in sites of prolonged venous hypertension has been noted.

Abnormalities in the physicochemical structure of the vessel wall or in its metabolic function are probably of major importance in the development of atherosclerosis. Actually relatively little is known concerning such abnormalities and therefore their relation to atherosclerosis has been neglected in comparison to recent emphasis on the possible role of abnormal lipid metabolism.

Assuming that atherosclerosis results from the deposition of lipids in the intima as plasma filters through the arterial wall, increased endothelial permeability or preceding arterial injury may predispose to such deposition of lipids. There is experimental evidence that a variety of types of preliminary vessel injury or other influences modifying structure or function, e.g., sympathectomy or aortic cauterization, have been shown to favor the localization of lipids in the affected area of the vessel and to accelerate the development of atherosclerosis.[44, 166, 199] The intense atherosclerosis found in regions of the aorta involved by syphilis is a striking example of the predisposing influence of underlying disease. If the initial lesion of atherosclerosis is one of intimal hyperplasia and the deposition of mucoid material secondary to the stress of intravascular pressure, such intimal alterations may determine the occurrence and localization of lipid deposits. Injury or change in the intimal elastic membrane may contribute to atherosclerosis since this membrane may act as a barrier to the passage of lipid through the arterial wall.

PATHOLOGY OF CORONARY ATHEROSCLEROSIS

Reviews of the historical development of our knowledge of coronary atherosclerosis have been presented by Benson[15] and by Long.[13] For a detailed description of the gross and microscopic alterations resulting from coronary atherosclerosis the reader is referred to Bork,[11] Jores,[100] Wolkoff,[39] Leary,[1] Glomset.[7, 48]

MICROSCOPIC APPEARANCE OF CORONARY ATHEROSCLEROSIS

The primary and predominant lesions occur in the intima *There is uncertainty as to the very earliest lesions* According to Klotz,[117] Leary[1??, 1 3] and others the initial change is the presence of lipid-containing macrophages (foam cells) in the subendothelial layer of the intima Shortly thereafter, if not simultaneously, there are deposits of lipoidal material in the ground substance of the intima as well as in the large mononuclear foam cells The initial foci of lipid within and outside the *macrophages coalesce to form lipid rich* intimal plaques Vacuolar degeneration and swelling of the metachromatic ground substance and collagen framework of the intima are also observed in early lesions According to Aschoff[11] and others[144] these changes, including the deposition of mucoid ground substance the formation of fibroblasts and collagen and the proliferation of elastic tissue, are primary and the deposition of *lipids secondary*

Subsequently thickening of the intima results from a proliferation of reactive or reparative connective tissue, from increased deposition of lipids within and outside of foam cells the formation of new capillaries, calcification and rarely bone formation The internal elastic lamella may be displaced and fragmented Sometimes it disappears while newly formed delicate elastic fibrils arise in the atherosclerotic plaque

The changes which follow the initial intimal lipoidosis and degeneration appear to represent attempts at repair or the consequences of disturbances in nutrition Normally the intima receives most or all of its nutrition by imbibition from the arterial lumen The *deposition of lipid and the formation of new* collagen to repair the damaged intima result in significant thickening of this layer of the artery In consequence, imbibition from the lumen even when supplemented by that from the adventitial vasa vasorum, is inadequate to nourish all portions of the thickened intima *Newly formed capillaries arise in the intima,* occasionally from the lumen, but more frequently from the vasa vasorum[8, ?] From this viewpoint the intimal capillaries represent a granulation tissue type of reparative structure designed to compensate for local nutritional deficiencies

Subsequent changes appear to be determined by the ability of these new nutritive channels to keep pace with increasing lipid and other degenerative changes and fibrosis A deficiency in nutrition results in necrosis of *the atherosclerotic plaque The latter, which is* filled with lipid becomes softened and forms the so-called atheroma, atheromatous abscess or cyst, which is composed of necrotic and degenerative tissue including cellular detritus, cholesterol esters and other lipids The atheromatous plaque often causes a unilateral thickening of the vessel wall and an eccentric lumen The atheroma may extend to the surface and rupture through the intima *emptying its contents into the lumen and* producing an atheromatous ulcer Calcium is deposited around the atheromatous focus as well as in the thickened fibrous hyalinized areas of the intima Large calcified plaques may result and occasionally bone is deposited in or replaces calcified areas Rupture of the intimal capillaries results in *localized hemorrhages* which may either advance the atherosclerotic process by increasing the circulatory *insufficiency or, more important may result* in acute coronary occlusion (p 500) Fibrinoid intimal masses often found in the region of atherosclerotic plaques may represent compressed and hyalinized elements of the blood due to such hemorrhage[11]

Changes in the media are much less prominent *and consist of atrophy of the muscular* and elastic elements This is probably the result of compression by the thickened intima The atrophic changes produce thinning and sometimes almost complete disappearance of the medial layer of the artery Fibrosis and hyalinization of the media are not uncommon in the region of the atherosclerotic plaque Occasionally lipoid material and calcium may be deposited in the media as well as in the intima, *especially when the frayed, fragmented* intimal elastic membrane is ruptured and permits the invasion of the media by the atheromatous material Sometimes capillaries may be seen extending from the adventitia through the media to the basal layers of the intima

The adventitial changes are less striking but frequently irregular patches of fibrosis and focal collections of lymphocytes simulate inflammatory lesions[64]

MACROSCOPIC PATHOLOGY

Mild lesions are represented by superficial *yellowish lipoid flecks, streaks or nodules on* the intimal surface or by small white patches

of fibrous thickening More advanced lesions cause pronounced thickening and rigidity of the vascular wall and thick lipoid, fibrous or calcified intimal plaques which protrude into and encroach on the lumen Atherosclerosis of the coronary arteries usually involves the epicardial branches without extending into the branches penetrating the myocardium The most advanced lesion in the epicardial vessel is on the surface nearest the muscle [48] Extreme degrees of narrowing may result, but evaluation of coronary stenosis at necropsy examination should make allowance for postmortem collapse [107] Extensive calcification of the coronary artery wall may produce a pipe-stem consistency Revascularization of the atheromatous plaques intimal hemorrhages and extension of intimal necrosis to the surface causing ulceration are among the common occurrences Blood platelet thrombi may be deposited in such atheromatous ulcers Zak and Elias [44] found evidence that extrusion of the contents of atheromata with resulting embolism to more distal positions of the coronary arteries is more common than has been suspected

The most serious complication of coronary atherosclerosis is thrombotic occlusion (for pathology see p 499) In addition atherosclerotic aneurysm and rupture occur rarely [183] Rupture of such an aneurysm may cause hemopericardium and fatal cardiac tamponade [166]

The Heart in Coronary Atherosclerosis

As a rule uncomplicated coronary atherosclerosis is unaccompanied by significant cardiac lesions unless the degree of narrowing of the vessels seriously impairs the blood supply to the myocardium In most instances actual occlusion of the vessel accounts for gross myocardial change (for pathology of the heart in coronary occlusion see p 501) Under certain circumstances prolonged coronary insufficiency can occur without coronary occlusion and the resultant myocardial anoxia may be followed by focal or extensive areas of subendocardial myocardial necrosis of the left ventricle and papillary muscles (p 505)

Frequently severe coronary atherosclerosis with narrowing but without occlusion is accompanied by fine diffuse fibrosis of the heart muscle confined essentially to the left ventricle and papillary muscles Of 37 cases of severe coronary atherosclerosis without occlusion Clawson[7] observed severe myocardial fibrosis of irregular distribution in 18 slight fibrosis in 17 and none in 2 These lesions are interpreted as fibrous replacement of myocardial fibers which atrophied or degenerated and disappeared as a result of ischemia The fibrosis is not a result of inflammation and therefore the term myocarditis is inappropriate Somewhat similar diffuse fibrosis may be observed as a result of longstanding ischemia in calcific aortic stenosis (p 701) and in cases of malignant hypertension

The heart is of normal size or slightly hypertrophied in uncomplicated coronary atherosclerosis Moderate left ventricular hypertrophy is frequently present because of an associated hypertension When coronary atherosclerosis with or without occlusion results in congestive heart failure pronounced dilatation and hypertrophy of the heart develop

PATHOLOGIC PHYSIOLOGY

Physiologic disturbances of the heart and clinical manifestations result when the atherosclerotic process seriously impairs the coronary blood supply to the myocardium This may occur in the following ways

(1) Atherosclerotic occlusion of an artery may lead to infarction of a portion of myocardium This is discussed below (p 497)

(2) Occlusion of an artery may result in chronic potential anoxia of a portion of myocardium The collateral circulation prevents infarction (see under angina pectoris p 455)

(3) Multiple coronary occlusions and myocardial infarctions heal but so impair cardiac structure and function as to cause heart failure

(4) Coronary atherosclerosis and narrowing insufficient in themselves to produce symptoms may cause coronary insufficiency and cardiac decompensation in a preexisting enlarged rheumatic syphilitic or hypertensive heart

(5) Extreme atherosclerotic coronary narrowing without occlusion may cause clinical evidence of coronary insufficiency when the demands of the heart muscle increase

(6) Atherosclerotic rigidity of the coronary vessels may impair their ability to adjust in caliber to changing cardiac demands for blood This is theoretical

It will be observed that atherosclerotic heart disease in the clinical sense results usually from recent or old coronary artery

occlusions and to a lesser extent from extreme coronary narrowing without occlusion Lesser degrees of interference with blood flow are rarely of physiologic or clinical significance

CLINICAL FEATURES

The clinical features of coronary heart disease may be classified into a variety of syndromes one or more of which may occur in the same patient at the same or different times during the course of the disease

1 Angina pectoris or cardiac pain
2 Acute coronary occlusion and myocardial infarction
3 Left-sided heart failure including cardiac asthma
4 Combined left and right sided heart failure
5 Heart block and other disturbances in conduction and rhythm
6 Gastrointestinal and substitution symptoms
7 Sudden death
8 Latent or asymptomatic cases

Angina Pectoris and Coronary Occlusion

Angina pectoris and acute coronary occlusion and myocardial infarction are the most frequent and important manifestations of coronary heart disease For this reason special chapters are devoted to their discussion (see Chapters 17 to 21)

Heart Failure

Manifestations of congestive heart failure (Chapter 7) may emerge after a previous history of angina pectoris or myocardial infarction or they may appear gradually or suddenly as the initial symptoms of coronary heart disease Heart failure may be viewed as the result of progressive coronary narrowing and insufficiency or of repeated myocardial infarcts When heart failure is the initial manifestation it is assumed either that progressive cardiac damage occurred without preceding acute localized areas of myocardial anoxia or infarction or that such episodes were clinically asymptomatic or unrecognized Frequently acute left ventricular failure (pulmonary edema) develops concomitantly with a clinical episode of acute myocardial infarction, or left- and right sided heart failure develops more or less rapidly after recovery from the attack

Left sided heart failure develops earlier and more commonly because the coronary arteries supplying the left ventricle are most affected by atherosclerosis infarcts are almost exclusively in the left ventricle and because the left ventricle performs more work and has a greater muscle mass and is therefore more susceptible to ischemia Frequently associated hypertension also contributes to the development of left ventricular failure in cases of atherosclerotic heart disease

Dyspnea on exertion or nocturnal attacks of cardiac asthma are the cardinal symptoms Frequently patients with coronary heart disease suffer from angina pectoris as well as heart failure, therefore cardiac pain and exertional dyspnea or nocturnal dyspnea may occur in the same patient Restriction of activity because of the pain may obscure exertional dyspnea Weakness is a frequent complaint Orthopnea and cough due to pulmonary congestion are common symptoms with advanced left-sided heart failure I have several times observed intractable cough as the dominant symptom of atherosclerotic heart disease Right sided heart failure, including peripheral edema hepatic enlargement and systemic venous engorgement often follows and is combined with evidence of left ventricular failure

Cardiac Arrhythmias

Heart block is an uncommon manifestation of coronary atherosclerosis even though the latter with or without occlusion is its most frequent cause Rarely heart block is the first or only evidence of an acute coronary occlusion (p 539) The heart block may be asymptomatic it may give rise to palpitation or precordial discomfort or it may be associated with Adams-Stokes syndrome (p 540) (For a detailed discussion of heart block see p 384)

Coronary heart disease is characterized by the frequency of disturbance in mechanism, i e in rate rhythm or rhythmicity, as well as in mechanical function as a pump Hence ventricular standstill and fibrillation are common at some time in the course of the disease and are often responsible for sudden death Frequently there is a discrepancy between the amount of anatomic disease with consequent symptoms of myocardial ischemia or heart failure and the disturbance in cardiac mechanism Unfortunately, disturbances in cardiac mechanism with a fatal outcome occur frequently when the extent of myocardial infarction or fibrosis would not have caused serious chronic cardiac disability

Bundle branch and intraventricular block (p 395) are more common and may be associated with atrioventricular block The former conduction disturbances do not produce symptoms, but angina pectoris or congestive heart failure is often present Not infrequently the finding of bundle branch or intraventricular block in asymptomatic persons is the sole clue to the presence of atherosclerotic heart disease But other causes of intraventricular block must be considered (e g calcific aortic stenosis gumma diphtheria rheumatic fever tumors or cysts drugs)

Atrial fibrillation occurs commonly in advanced cases of atherosclerotic heart disease with congestive heart failure The occurrence of atrial fibrillation may be the first evidence which leads to the discovery of previously unrecognized atherosclerotic heart disease Premature beats are common but not characteristic of this disease

Digestive disturbances may be prominent symptoms of coronary heart disease The resemblance of acute myocardial infarction to an acute attack of indigestion is well known Gaseous eructations may accompany or follow paroxysms of angina pectoris The development of digestive disturbances predominantly on exertion should suggest coronary insufficiency Postprandial abdominal fullness meteorism belching and flatulence may be due to chronic cholecystitis or functional digestive disturbances but may also result from coronary heart disease Digestive disturbances in this type of heart disease may also be due to heart failure (p 155) or to overdosage with digitalis (p 264)

Sudden death (p 316) is due most commonly to coronary heart disease if accidents and poisonings are excluded It is a common termination in cases of angina pectoris and is often associated with acute coronary occlusion (p 513) But sudden death may complicate coronary heart disease without the occurrence of an acute occlusion[378] Coronary atherosclerosis with pronounced coronary narrowing but no occlusion or infarction was observed by French and Dock[59] in many cases of sudden death in young soldiers Under the heading of acute fatal coronary insufficiency Levy and Bruenn[1 6] described a series of hospitalized patients with coronary heart disease who died suddenly and who at postmortem examination presented coronary atherosclerosis but no fresh occlusion or other anatomic lesion to explain the immediate cause of death They observed an 11 8 per cent incidence of sudden death in a group of patients with coronary sclerosis without thrombosis as compared with 33 3 per cent in a similar group with coronary thrombosis Sudden death occurred in 27 5 per cent of those patients who presented a history of cardiac pain and in 9 1 per cent of those without such pain Sudden death in coronary heart disease is usually attributed to ventricular fibrillation cardiac standstill acute massive pulmonary embolism or cardiac rupture following acute myocardial infarction

Finally coronary heart disease may be asymptomatic for long periods of time its presence being indicated by a past history of angina pectoris or myocardial infarction or by electrocardiographic abnormalities (see below)

DIAGNOSIS OF CORONARY (ATHEROSCLEROTIC) HEART DISEASE

The diagnosis of coronary heart disease is based most often on a past or present history of acute myocardial infarction or of angina pectoris Other causes of angina pectoris such as calcific aortic stenosis (p 700) syphilitic ostial stenosis (p 896) or extreme anemia are usually relatively easy to distinguish

In the absence of myocardial infarction or angina pectoris the diagnosis of coronary heart disease is always uncertain but may be presumed if manifestations of congestive heart failure especially cardiac asthma or pulmonary edema appear in patients past 45 years of age who present no other apparent cause for these symptoms Electrocardiographic changes (see below) suggestive of recent or old myocardial infarction lend support to the diagnosis Attacks of Adams Stokes syndrome are usually indicative of atherosclerotic heart disease

Electrocardiographic Changes

Electrocardiographic abnormalities may be absent in one quarter to one half of the cases of coronary heart disease especially in those characterized only by angina pectoris Sometimes a presumptive diagnosis of coronary heart disease is justifiable on the basis of routine electrocardiographic findings The distinctive electrocardiographic abnormalities of acute myocardial infarction (p 521) are of course diagnostic Healed infarction may be disclosed by persistent M or W shaped QRS complexes in lead I or II by the

presence of a large Q and an inverted T wave in lead I or by similar findings in leads II and III, or by absence of R waves and inverted T waves in precordial leads over the left ventricle.

T wave inversions often denote myocardial impairment due to coronary atherosclerosis but may be due to a variety of other causes[1,4] which can often be excluded. S-T interval deviations may be associated. Inversion of T_1 and especially of T_1 and T_2 are much more significant than isolated inversion of T_3. *Inversion of the T wave in the precordial* leads occurs commonly in coronary heart disease and is usually more striking than in the standard leads.[72] But T wave inversions may result from positional deviation of the electrical axis of the heart or from cardiac hypertrophy due to causes other than coronary atherosclerosis. Inversion of T_3 is common in obese individuals or as a result of *other factors which elevate the diaphragm or* produce a transverse position of the heart. Occasionally T_2 as well as T_3 may become inverted as a result of respiratory or postural changes. Inversion of T_1 with depression of ST_1 and left axis deviation is common with severe hypertension[13] and may not necessarily denote coronary heart disease. Digitalis causes pronounced T wave inversions and S-T depressions which are often distinctive (p. 269). T wave inversions due to pericarditis, a variety of acute infections or toxic or nutritional disturbances can usually be differentiated by the clinical history. S-T interval depressions and/or lowering or inversion of T waves appearing after an exercise or anoxemia test are strongly confirmative of coronary heart disease (coronary insufficiency) *when there is a clinical suspicion of that condition or the clinical features are atypical.* RS-T segment coving and frank T wave inversions in the mid- and left precordial leads may occur in anxious, tense individuals, especially Negroes, without other evidence of heart disease.[7,38] Such changes have been attributed to hyperventilation or to vagal reflexes. The administration of the vagal blocking agent *Pro-Banthine results in prompt normaliza*tion of the electrocardiographic abnormalities.

Q waves may be indicative of coronary heart disease. Often they persist with or without T wave inversion, as the residua of a previous cardiac infarction. A large Q_3, often associated with a Q_2, may persist after infarction of the posterior wall of the left ventricle, but a Q wave is often present in lead III in normal individuals. According to Pardee[165] and Durant[50] *a Q_3 is significant of myocardial damage* only if the voltage of the Q wave is at least one-fourth as great as that of the tallest QRS complex in any standard lead and if a Q_2 of at least 1 mm. is also present. Durant[50] found that the significance of a Q_3 as an indicator of coronary heart disease was enhanced if: (a) Q_3 was at least half as large as the tallest R, (b) Q_2 was at least one quarter as large as R_2 *and (c) there was no right axis deviation.* A Q_3 prolonged to more than 0.04 second is suggestive of coronary heart disease. Differentiation of normal from abnormal Q waves in lead III has been facilitated by the use of an augmented unipolar left leg lead.[184]

Both with respect to T and ST abnormalities and to the finding of Q waves, their significance in the diagnosis of coronary heart *disease increases if they disclose progressive* change in repeated observations over a period of months or years.[26]

Conduction disturbances are often suggestive of coronary heart disease when they are observed in middle-aged or older individuals and if rheumatic heart disease, syphilitic heart disease, congenital cardiovascular disease, diphtheria and other infections and drugs *such as digitalis or quinidine can be excluded* as etiologic factors. Such exclusion is often possible on the basis of the history, physical examinations and laboratory tests. Partial or complete heart block may be observed in patients with old and often unrecognized coronary occlusions or in cases of severe but nonocclusive coronary atherosclerosis. Bundle branch block, especially of the left bundle, and intraventricular conduction *defects,* characterized by widening of the QRS interval to 0.12 second or more and by slurring and notching of the QRS waves, are usually diagnostic of coronary heart disease. But rheumatic fever, diphtheria, congenital lesions, quinidine and the Wolff-Parkinson-White syndrome must be excluded. Low voltage, with or without slurring of the QRS complexes *in leads I and II, often with low or in*verted T waves, is suggestive of coronary heart disease if myxedema, constrictive pericarditis and pericardial effusion can be excluded. QRS complexes which are of low voltage, slurred and notched only in lead *III* or in right precordial leads are usually insig

nificant But notching of the R wave especially near the apex in leads I and II is indicative of myocardial damage usually due to coronary athero clerosis

Roentgenologic examination may help in the diagnosis Occasionally an enlarged cardiac silhouette is the first clue to the presence of unrecognized coronary heart disease which is then confirmed by a careful history or electrocardiographic examination Absence or reversal of left ventricular pulsation discovered by fluoroscopy may similarly suggest or add support to a diagnosis of coronary heart disease with old infarction and possible ventricular aneurysm The roentgenogram may reveal calcification of the coronary arteries which appear as linear and segmental streaks in curves corresponding to the course of the vessels[36] Calcification denotes coronary atherosclerosis but not necessarily clinical coronary heart disease

Summary of Diagnostic Features

1 Clinical or electrocardiographic evidence of a recent or past attack of myocardial infarction warrants a diagnosis of coronary heart disease

2 Angina pectoris usually denotes coronary heart disease but less common causes of this syndrome must be excluded

3 Electrocardiographic abnormalities including T wave inversions and ST deviations the presence of Q waves and atrioventricular and intraventricular conduction disturbances often permit a presumptive diagnosis of coronary heart disease if due regard is given to the age and clinical history of the patient and if other causes of such electrocardiographic changes can be reasonably excluded

4 Cardiac enlargement and congestive heart failure in middle aged or elderly subjects may suggest the presence of coronary heart disease but these abnormalities should provoke a careful review of the history and findings on physical and electrocardiographic examination in an effort to confirm the diagnosis or discover other etiologic factors

Certain misconceptions regarding the diagnosis of coronary heart disease should be dispelled Heart failure or other abnormal cardiac findings are not necessarily due to coronary heart disease merely because the patient is past 50 or past 60 years of age neither does youth exclude this diagnosis The finding of arteriosclerotic radial arteries or of atherosclerosis of the aorta lower extremities or the retinal vessels does not denote that coronary heart disease is also present Coronary (atherosclerotic) heart disease is not excluded because of the absence of physical signs in the heart or because of a normal cardiac size or a normal electrocardiogram

PROGNOSIS

The course and prognosis of coronary heart diseases has been studied best in connection with its most specific manifestations viz cardiac infarction angina pectoris heart failure bundle branch block and is discussed in detail under these individual headings

TREATMENT

The treatment of coronary heart disease is essentially that of its specific manifestations such as heart failure (p 234) myocardial infarction (p 562) angina pectoris (p 470) or the various arrhythmias To avoid repetition I refer the reader to these headings

Theoretically it would be desirable to direct treatment against the basic cause namely atherosclerosis Most of the measures designed to prevent retard or diminish human coronary atherosclerosis are presumed to act by modifying cholesterol metabolism or diminishing cholesterol absorption thereby reducing the serum cholesterol Or agents have been used to stabilize cholesterol solubility in the blood thereby diminishing its deposition in the arterial intima The therapeutic rationale assumes that an abnormal level of serum cholesterol or of lipoproteins containing the cholesterol or an abnormal state of serum lipid solubility is the major factor in the development of atherosclerosis Among the therapeutic measures which have been considered for their possible effect in reducing or stabilizing serum cholesterol or otherwise opposing atherosclerosis are (1) weight reduction by low calorie diet (2) low fat and/or low cholesterol diets (3) plant sterols sitosterol or specific vegetable fats dihydrocholesterol and other cholesterol analogues (4) lipotropic agents heparin like substances (5) detergents (6) estrogens (7) iodides and thyroid extract

The efficacy of any of these measures with regard to the prevention or treatment of human coronary atherosclerosis is as yet unproven From the viewpoint of clinical practice there is *no acceptable specific treatment* of coronary atherosclerosis Many of the

recommended measures deserve and are undergoing further investigation. Unfortunately it is difficult to evaluate clinical therapeutic studies because there is no convenient accurate method of evaluating the presence, degree or progression of human coronary atherosclerosis. Furthermore because of the long duration and the clinical variation of the natural life history of coronary atherosclerosis, very large numbers of cases and very prolonged periods of observation are necessary. The following individual therapeutic measures are discussed not because they are recommended but because the problem of whether to prescribe them arises frequently in clinical practice.

1 Weight Reduction. Low Calorie Diet

There is more general agreement as to the desirability of weight reduction by a low calorie diet than as to any reduction in specific dietary factors such as cholesterol or fat. The prevalance of coronary atherosclerosis has been correlated with obesity and high caloric intake.[30, 1, 45] On the other hand coronary heart disease also occurs frequently in patients who are not overweight and epidemiologic studies have indicated that obesity occurs as commonly in Bantus or southern Italians who are relatively free of coronary atherosclerosis as among Americans or Swedes with a high incidence of coronary atherosclerotic heart disease. Walker and associates[1] reported that an average weight loss of 19 pounds in 39 subjects led to a reduction in total serum cholesterol and in the atherogenic S_f12–20, 21–35 and 35–100 classes of lipoproteins in most cases, but other observers found no reduction in serum cholesterol or other lipids following weight reduction.[143, 171] It should be reemphasized however that the level of serum cholesterol or lipoproteins has not been proved to be an accurate index of atherosclerosis and that a therapeutic measure may be beneficial for coronary atherosclerosis even when it does not modify the serum lipids.

Weight reduction should be recommended for all overweight patients with coronary heart disease. Clinical impressions and statistical data suggest that weight reduction is beneficial for well being and longevity; therefore it may be regarded as good therapeutic advice whether or not its benefit is due to a favorable effect in retarding or diminishing coronary atherosclerosis.

It is probably desirable to diminish obesity *gradually* by a moderate reduction in caloric intake especially of fats. During very rapid weight reduction utilization of the patient's own fat is tantamount to a high fat diet. I have been impressed by the number of instances in which an acute myocardial infarction followed a period of rapid weight reduction. As a rule these patients reduced their weight by following a very high animal protein low carbohydrate diet. The distribution of calories as well as the low calorie diet may be important when weight is being reduced to prevent or retard coronary atherosclerosis.

2 Low Cholesterol or Low Fat Diets

A low cholesterol diet has been recommended because of the evidence relating cholesterol feeding and hypercholesterolemia to atherosclerosis. Attention has been directed to the difficulty of reducing the serum cholesterol significantly and continuously in man by a low cholesterol intake (p 424) presumably because of endogenous cholesterol formation from 2-carbon fragments derived from carbohydrates, fats or proteins. Most of the so-called low cholesterol diets prescribed by physicians are incapable of modifying the serum cholesterol.

To reduce significantly serum cholesterol by diet requires not only a low cholesterol but particularly a very low fat diet not exceeding 20 gm daily.[110] Such a low cholesterol low fat diet is the rice-fruit diet of Kempner which is free of cholesterol and contains not more than 5 gm of fat. Kempner[108] reported an average reduction of 74 mg per 100 cc (27%) in hypercholesteremic and 15 mg per 100 cc (8%) in normocholesteremic patients on the rice diet and similar findings were reported by Starke.[207] Watkin et al[224] reported that in 41 patients with essential hypertension in the second month of treatment with the rice diet there was a mean decline of 40 mg per 100 cc (17%) in serum total cholesterol, due chiefly to a reduction in the cholesterol ester fraction. But in 45 per cent of the cases there was either no significant decrease in serum cholesterol or the early decline was not sustained. Gofman and his associates[76] reported that very low cholesterol diets reduce the concentration of the S_f12–20 "atherogenic" lipoprotein aggregates. But Hatch and associates[83] reported no significant change in the S_f12–20 and a mean 100 per cent *increase* in the concentration of the S_f20 to

100 lipoprotein fractions on the rice diet with considerable variation among individual subjects The impalatability of such an extreme dietary regimen as the unmodified rice fruit diet imposes too great a hardship to permit prolonged use by the vast majority of patients In view of the inconstant and relatively small and frequently transient reduction in serum cholesterol induced by such a low cholesterol diet and the unproven benefit in preventing or reversing coronary atherosclerosis the prescription of such a low cholesterol diet cannot be regarded as warranted at the present time

Of even greater significance is the evidence that the control of serum lipid levels and the geographic or ethnic distribution of human coronary atherosclerosis is related to the fat intake and not to that of cholesterol, or else that a low cholesterol diet is of benefit only when fats are also greatly restricted[116, 86] Direct evidence of the benefit of low cholesterol and low fat intake was reported by Morrison[119] Fifty patients recently recovered from a proven attack of acute myocardial infarction were placed on a low cholesterol low fat diet (20 to 25 gm daily) and observed for 8 years while 50 similar patients were maintained as controls on their ordinary diet The mortality rate was 76 per cent in the control group 44 per cent in the group on the low cholesterol diet All serum lipid fractions were reduced Attacks of angina pectoris decreased in severity and frequency and exercise tolerance increased in the group in low cholesterol intake However it is questionable whether a significant conclusion can be drawn from this study

A list of foods relatively rich in cholesterol stresses dairy products and raises the question of a possible causal relation between the increased intake of dairy products in countries with the highest incidence of coronary atherosclerosis (e g the United States Great Britain Denmark) The following foods are *cholesterol rich*

1 Whole milk cream cheese and cheese spreads butter ice cream
2 Egg yolk
3 Liver brains heart, kidney sweetbreads fish roe
4 Animal fats such as fatty meats pork bacon lard fatty fish (salmon mackerel, tuna whitefish)
5 Oysters shrimps brewers yeast
6 Salad dressings containing olive oil rich gravies olives nuts avocados
7 Cream soups
8 Hot breads pancakes waffles many puddings coffee cakes muffins doughnuts
9 Desserts made with cream or egg yolks pies frozen creams

Even neutral fats are undesirable in low cholesterol diets because they aid the absorption of cholesterol In this respect vegetable fats may act like animal fats

A *cholesterol poor diet* permits

1 Skimmed milk and buttermilk without fat
2 Whites of egg
3 Lean meats and lean fish (in small quantities)
4 Fat-free broth bouillon or soups
5 Cooked and raw vegetables
6 Fruits
7 Cooked or dry cereals
8 Salads with salad dressings of mineral oil lemon juice vinegar ketchup spices
9 Tea coffee tomato juice sugar jellies
10 Breads with oleomargarine potatoes according to desired caloric and fat intake

Chocolate lard margarine hydrogenated fats and salad oils are high in fat but not in cholesterol It should be stressed that present evidence does not clearly indicate whether all fats or only animal fats should be curtailed in the diet of the patient with clinical coronary disease Excessive caloric intake should be avoided and fats should provide no more than 20 to 25 per cent of total calories

3 *Plant Sterols*

The plant sterol sitosterol was found to lower serum cholesterol in chicks[169] and man[176] and to decrease the incidence of atherosclerosis in cholesterol fed rabbits[174] and chicks[169] Sitosterol is presumed to act by interfering with the absorption of dietary cholesterol and cholesterol excreted by the liver into the gastrointestinal tract perhaps by competing for esterification[93, ...] Best and associates[19] observed a sustained reduction of serum total cholesterol cholesterol lipid phosphorus ratio and so-called atherogenic Sf 10-100 lipoprotein aggregates when 20 to 25 gm beta sitosterol was administered daily in divided doses before meals to 14 subjects on free diets Similarly Farquhar and Smith[55] observed that the administration of 9 to 18

gm daily of beta sitosterol to 15 normotensive, non-diabetic men who had previous myocardial infarction resulted in a significant fall in serum cholesterol total lipid and beta lipoprotein lipid with insignificant change in alpha lipoprotein Whether this has any practical application to the control of coronary atherosclerosis is unproven at this time More recently Ahrens and associates[4] fed a variety of single well defined fats of plant and animal origin to 3 normocholesteremic and 4 hypercholesteremic patients A reduction in serum lipids was most striking during the intake of corn oil as compared with olive lard or coconut oil They concluded that the reduction in lipid levels following feeding of plant fats was dependent on the specific fat which was fed and not on the decreased intake of cholesterol The effect was not due to the sitosterol content of the corn oil

In addition to the sitosterols and corn oil other substances have been administered in an effort to reduce the serum cholesterol by interfering with cholesterol absorption e g , dihydrocholesterol the cholesterol analogue cholesteryl chloride, and cholesterol free lipid poor brain extracts There is inadequate justification for the clinical administration of any of the substances listed under this heading

4 Lipotropic Agents

There is little basis for the therapeutic use of the lipotropic agents choline, methionine and inositol Yet they are widely prescribed in clinical practice for the prevention and treatment of coronary heart disease These agents have been shown to be effective in preventing or reversing the fatty degeneration of the liver associated with certain nutritional deficiencies, but experimental evidence regarding the effect of lipotropic agents on serum lipids and atherosclerosis is inconclusive and controversial[152 200 41 39 22] Because the lipotropic substances constitute an important part of the phospholipids, it was thought that they might aid in stabilizing the colloid dispersion of plasma cholesterol, but there is no direct evidence that they accomplish this when given orally A depression of serum cholesterol has been reported in patients with hypercholesterolemia who had survived a myocardial infarct and were given inositol for eight weeks[57] Morrison[158] has claimed that lipotropic agents elevated the serum phospholipids and thus reduced the serum cholesterol phospholipid ratio in patients with coronary heart disease provided that they adhered to a low cholesterol, low fat intake (20 to 25 gm fat daily) and that large doses of the lipotropic agents were given for at least six months Despite these and similar claims which are based on unconvincing clinical observations critical analysis of available studies indicates that lipotropic agents are ineffective in the treatment of coronary atherosclerosis[101]

5 Heparin and Heparin-Related Substances

The clearing effect of injected heparin on lipemic blood plasma and its reported beneficial effect on blood lipoproteins and experimental atherosclerosis (p 422) suggested its clinical use in coronary heart disease Its reported beneficial effect on angina pectoris will be discussed (p 482) At the present time there is insufficient evidence to justify the use of heparin for the treatment of coronary atherosclerosis even though Engelberg et al[65] reported that the subcutaneous administration of 200 mg of heparin twice weekly to 105 patients with a previous myocardial infarction was followed by only 4 cardiovascular deaths over a two year period, whereas there were 21 deaths among a control group of 117 patients with previous myocardial infarction who did not receive heparin

6 Detergents

Despite the reports of the beneficial influence of surface-active detergents on blood lipids and experimental atherosclerosis (p 422) there is no evidence to justify their clinical use to control coronary atherosclerosis

7 Estrogens

The evidence relating the sex hormones to experimental and human atherosclerosis has been presented (pp 427-8) The presumably favorable influence of estrogens on the serum lipids and lipoproteins of survivors of myocardial infarction[15] was effected by large doses which were accompanied by usually intolerable side effects These included swelling of the breasts, loss of libido, impotence, depression and irritability The administration of androgens to neutralize these side effects resulted also in an abolition of the desired estrogen effects on serum lipids The use of estrogens for the specific treatment of coronary atherosclerosis in clinical practice is unwarranted at present

6 Thyroid Extract and Iodides

The relationships between thyroid hormones and blood cholesterol and experimental atherosclerosis have been presented (p 428). These relationships have suggested the possible value of administering thyroid extract to patients with clinical evidence of coronary atherosclerosis. Although thyroid extract has been administered empirically, its value has not been established.

Similarly iodides have been administered empirically without proof of clinical benefit, based largely on the inhibitory effect of iodides on experimentally induced atherosclerosis in cholesterol fed animals.

OTHER DISEASES OF THE CORONARY ARTERIES

Disease of the coronary arteries may be due to a variety of other causes as well as to atherosclerosis. The principal causes include

1. Atherosclerosis
2. Syphilis
3. Rheumatic fever
4. Other infections
5. Periarteritis nodosa
6. Embolism
7. Aneurysm
8. Trauma
9. Congenital abnormalities
10. Thromboangiitis obliterans
11. Medial calcification

For the most part these conditions produce only pathologic anatomic lesions which may be entirely asymptomatic. Clinical manifestations of heart disease may result when these lesions interfere significantly with the vascular supply of a portion of the myocardium or when rupture of a coronary artery and consequent hemorrhage are followed by hemopericardium and cardiac tamponade. Thus a clear distinction must be made between coronary artery disease representing asymptomatic anatomic lesions and clinical forms of heart disease due to coronary artery disease and its resulting myocardial damage.

1 Coronary atherosclerosis has been discussed.

2 Syphilis of the coronary arteries is discussed in the chapter on cardiovascular syphilis (p 894).

3 Rheumatic fever is associated frequently with lesions of the coronary arteries but these are almost always microscopic and not responsible for clinical findings (p 819).

4 Other Infections

Inflammatory changes of the coronary arteries with granular degeneration, cellular infiltration, atrophy and fibrosis were noted by Wiesel [7] and by Wiesner [3] in a variety of infectious diseases, especially diphtheria and scarlet fever, but also typhoid fever, influenza, pneumonia and pyogenic infections. As a rule the lesions were visible only microscopically and affected the media predominantly. But they occasionally extended to the intima where they were grossly visible as minute slightly elevated yellow plaques. The significance and frequency of these lesions were minimized by Scharpff [133].

In cases of *typhus fever* the capillaries and arterioles of the heart, as well as of other organs, suffer from severe necrosis and thrombosis [84] but the larger coronary arteries are not significantly affected (p 915).

Destructive inflammatory changes in the coronary arteries occasionally result from general infections with bacteremia, especially in cases of *bacterial endocarditis* (p 868). Bacterial infection of the wall may cause a mycotic aneurysm. Minute infarcts due to bacterial emboli occur in a high percentage of cases [30].

Tuberculous arteritis involving the small coronary artery branches and arterioles was noted by Gouley and associates[71] in 5 of their 6 cases of myocardial tuberculosis. Most often there was an intimal thickening with little or no cellular proliferation. This led to almost complete obliteration of some small vessels. Occasionally there were intimal tubercles. In one case there was extensive destruction of the large coronary arteries and veins by direct invasion of tuberculous inflammatory tissue.

The lesions of the coronary arteries associated with infectious diseases other than syphilis rarely lead to coronary occlusion [151, 18] but in a case of Salmonella choleraesuis infection[34] an arteritis with thrombosis caused occlusion of the left anterior descending coronary artery with infarction of the left ventricle. The electrocardiogram showed the classic pattern of anterior wall infarction (p 525). The coronary arteries were said to be involved in one quarter of the cases of brucellosis studied by Manchester [17].

5 Periarteritis (Polyarteritis) Nodosa (Necrotizing Arteritis)

The coronary arteries are affected in 60 to 70 per cent of that motley group of cases

known as periarteritis nodosa [1,7,81,155] They were involved in 11 out of 15 cases reported by Spiegel [158] The lesions are characterized by inflammation, necrosis and eosinophilic degeneration of the media and adventitia, and a periarterial inflammatory reaction Often the necrotic wall yields and gives rise to nodular aneurysms The term periarteritis nodosa as used by Kussmaul and Maier[119] may be applied properly only to *those cases in which there are grossly visible* circumscribed nodular thickenings of the arteries, but in recent years cases have been included in which there is merely a microscopic necrotizing arteritis and periarteritis (polyarteritis nodosa) Healing may occur with fibrosis of the vessel wall [20]

Often the inflammatory lesion extends to the intima and may occasionally be complicated by thrombosis Thrombosis of a large coronary vessel may result in myocardial infarction and a clinical picture resembling that due to acute atherosclerotic coronary occlusion [80] I have seen one case in which there was massive infarction of the right atrium But myocardial infarction is rare either because the occluded vessel is small or because the occlusion evolves so gradually that an adequate collateral circulation develops In such cases there may be no clinical *symptoms or only those of mild coronary in*sufficiency, the electrocardiogram may disclose T wave inversions [1,7] Hypertension eventually develops in most cases of periarteritis nodosa and may account for cardiac enlargement and electrocardiographic evidence of left ventricular strain Congestive heart failure is a common terminal event [155] When there are gross aneurysms due to necrotizing arteritis, there are usually no clinical manifestations Occasionally an aneurysm ruptures and results in hemopericardium which may be fatal [194] In one case which I observed this complication was overshadowed by an associated perirenal hematoma and uremia In 4 cases which I reported with Gross [60] the lesions of necrotizing arteritis were accompanied by typical endo myo-pericardial lesions of acute rheumatic fever A granulomatous coronary arteritis has been reported in association with temporal arteritis [35,150] In one case the coronary arteritis was associated with myocardial infarction

6 Coronary Embolism

Coronary embolism is said to be relatively rare [187] Hamman[86] collected 30 reported cases of embolic occlusion of large coronary branches and added 10 additional ones from the pathologic records of the Johns Hopkins Hospital These undoubtedly represent a small fraction of the actual cases which are unreported in medical literature Moragues et al [146] reviewed the literature up to 1950 The following are the usual varieties of coronary embolism

(a) Fragments of valve vegetation usually bacterial
(b) Blood platelet thrombus
(c) Fat embolism
(d) Air (gas) embolism

(a) The most commonly recognized type of coronary embolism is that associated with subacute or acute bacterial endocarditis Almost 50 per cent of the cases studied by Hamman[86] fell into this group Sudden or even instantaneous death usually occurs if the embolus occludes a major artery or the coronary ostium but sometimes the survival period is long enough for the formation of a myocardial infarct bland or septic

In the first case of clinically diagnosed acute coronary occlusion recorded by Hammer[87] in 1878, the occlusion was probably due to bacterial embolism of the coronary artery *arising in bacterial vegetations of the aortic* valve and sinus of Valsalva In this case diagnosis was possible because the patient lived for 10 hours after the occlusion Cheng et al [30] reported a proven case of coronary embolism diagnosed during life, in which the source of the embolism was a left atrial thrombus Rarely, when a coronary ostium is blocked by a polypoid vegetation, the occlusion may be intermittent with consequent intermittent attacks of cardiac pain

As a rule bacterial emboli are multiple and of minute size and reach the small coronary arterial branches or arterioles These produce numerous scattered small infarcts and focal inflammatory lesions, which may result in miliary abscesses (p 868) In occasional instances the bacterial emboli produce a small subepicardial myocardial abscess which may rupture into the pericardial cavity and give rise to a clinically recognizable pericarditis

(b) Next in frequency are coronary emboli consisting of bland blood thrombi These arise in thrombi deposited on aortic atherosclerotic plaques in the sinus of Valsalva or

immediately above it in mural thrombi on the left side of the heart in thrombi of the coronary arteries or in peripheral venous thrombi *The mural thrombi at the root of the* aorta may themselves block a coronary ostium or give rise to a major coronary embolus or both As a rule these thrombi are situated on atherosclerotic plaques but occasionally the underlying disease is due to syphilis as in the cases reported by Porter and Vaughan[174] In most of the reported cases the patients were males between 25 and 35 without clinical evidence of cardiac disease in whom death occurred suddenly

Mural thrombi on the left side of the heart may give rise to one or two emboli of major coronary branches or numerous emboli in small branches Myocardial infarction with its distinctive clinical picture is more frequent in the reported cases of embolism from mural thrombi than in coronary emboli from other sources Mural cardiac thrombi give rise to coronary *emboli much more rarely than to* cerebral or other visceral emboli the latter lesions usually determine the clinical picture When numerous small coronary emboli arise from mural thrombi they may produce multiple small infarcts with eventual extensive myocardial fibrosis and heart failure[86]

Peripheral venous thrombi give rise to coronary emboli only in the presence of a functionally patent foramen ovale since the embolus must cross from the venous to the arterial side of the circulation (paradoxical or crossed emboli) Pulmonary emboli are usually present at the same time The paradoxical emboli occlude the cerebral vessels much more often than the coronaries In instances of pulmonary suppuration or neoplasm emboli may arise from an affected pulmonary vein and cause cerebral abscess or metastasis *and perhaps very rarely coronary* embolism

Both the pathologic and clinical diagnosis of these forms of coronary embolism is difficult In the bacterial form the pathologic diagnosis can usually be made by demonstrating the source of the embolus in the valvular vegetations the similarity of structure of the embolus and bacterial vegetation and the relative normalcy of the coronary wall in the vicinity of the embolus The pathologic distinction between bland blood clot coronary emboli and thrombi is even more difficult

The clinical diagnosis is rarely made but may be suggested when death occurs instantaneously in cases of bacterial endocarditis *Sometimes however as in 3 cases re*ported by Garvin and Work[illegible] death occurs more or less gradually in 2 of them there was septic myocardial infarction 1 with distinctive clinical and electrocardiographic features

(c) Fat embolism of the coronary arterioles and capillaries either produces no clinical consequences or they are overshadowed by the manifestations of pulmonary fat emboli

(d) Air embolism of the small coronary vessels is also discussed later (p 967) It is uncertain whether the air emboli in the coronary vessels are responsible for any of the clinical manifestations the latter are usually due to emboli in the cerebral and pulmonary vessels[154]

Rarer forms of coronary emboli have been observed Thompson and Evans[15] reported a *case of solid tumor emboli in both coronary* arteries arising from a malignant teratoma of the testes which had entered a vein and crossed to the arterial side (paradoxical embolism) by way of a patent foramen ovale A mass of tumor tissue was seen projecting through the latter Merkel[129] reported the occlusion of a coronary artery by *Plasmodium falciparum* with resulting myocardial infarction

7 Coronary Aneurysms

Aneurysms of the coronary arteries are rare They are believed to be due to (a) periarteritis nodosa (necrotizing arteritis) (b) bacterial endocarditis or other generalized bacterial infections (c) atherosclerosis (d) congenital abnormality and in isolated instances to syphilis[161] trauma or rheumatic fever Dissecting aneurysm of the aorta may *extend into the coronary artery*[213] *or involve* its orifice[1,2] The most frequent cause of coronary aneurysm is probably periarteritis nodosa In these cases the aneurysms are often multiple and involve several branches

Excluding this type Packard and Wechsler[161] collected 29 cases from the literature and added one of their own subsequent reviews have brought the number up to 50[191, 216, 213] Most of these were congenital The aneurysms were three times as common in males as in females In the majority the aneurysm was single and involved the first inch of the left coronary artery However

aneurysms of the right coronary artery may have been more readily overlooked although several instances have been reported[76, 110]

Bacterial (mycotic) aneurysms arise either by bacterial embolization or more often by direct implantation of bacteria without embolic vegetation on the intima A secondary necrotizing or suppurative arteritis with weakening of the wall leads to aneurysm Such aneurysms are much more frequent in other vessels especially the cerebral

Atherosclerotic aneurysm of the coronary artery is the commonest form after the age of 50[111] Usually the aneurysm is associated with coronary sclerosis and narrowing Rukstinat[185] reported multiple atherosclerotic aneurysms of the right coronary artery

In 25 to 50 per cent of the last two groups (bacterial or atherosclerotic) the aneurysm ruptures and causes sudden death due to hemorrhage or hemopericardium and acute tamponade The rupture usually occurs first into the periaortic space and thence into the pericardial sac In the atherosclerotic cases associated coronary thrombosis and congestive heart failure are equally common causes of death

In one case of aneurysm of a coronary artery there was an arteriovenous fistula formed by a dilated atherosclerotic vessel communicating with the coronary artery and the right atrium[3]

8 Traumatic lesions of the coronary arteries are discussed in Chapter 45

9 Congenital coronary lesions **(p 791)**

10 *Thromboangiitis Obliterans*

Although the incidence of coronary disease and coronary occlusion in cases of thromboangiitis obliterans is said to be higher than is usual for the age group affected no indubitable case of thromboangiitis obliterans involving the coronary arteries has been reported However Saphir[■] in a review of 30 cases of thromboangiitis obliterans from the literature with special emphasis on the coronary changes reported 1 case in which he stated that the characteristic abnormalities seen in the extremities were also present in the coronary arteries These consisted of acute inflammation of all the layers of the vessels including veins as well as arteries miliary lesions with accumulations of polymorphonuclear leukocytes histiocytes and giant cells and *thrombus formation* *Lesions of coronary atherosclerosis* were found associated with these inflammatory changes

The patient, a 35 year old male after suffering for six years from the characteristic symptoms of intermittent claudication suddenly collapsed and died instantly Necropsy examination revealed multiple small cardiac infarcts and myocardial fibrosis in addition to the coronary lesions

11 *Medial calcification of the coronary arteries* with fibroplastic proliferation of the intima[210] also described as medial coronary sclerosis[■] apparently constitutes a distinct pathologic condition All the cases involve children less than twenty-seven months old There is an equal distribution between the sexes The media of the larger coronary arteries are extensively involved and the intimal proliferation may be sufficient to occlude the artery The cause is unknown but in some cases there were also severe renal lesions The lesions may be due to metastatic calcification as in cases of renal rickets hyperparathyroidism etc

Chapter 17

ANGINA PECTORIS

Clinical Features, Etiology and Pathogenesis

The term angina pectoris was introduced by Heberden[43] (1768) to designate a very distinctive "disorder of the breast" attended with "a sense of strangling and anxiety." By using the word angina (strangling) it is clear that Heberden differentiated angina pectoris from multiple forms of chest pains of varied etiology, which were loosely assembled under the heading of *dolor pectoris*. Heberden described angina pectoris as a special disturbance in which the chest pain was of a peculiar modality and was often accompanied by psychic phenomena, most striking of which was a fear of impending death (angor animi). He noted that the pain generally occurred in paroxysms and that those afflicted with it were seized usually while walking, especially after a heavy meal, with an insupportable pain over the sternal region which rapidly vanished when the sufferer rested. There was no associated breathlessness. Those subject to angina pectoris were apparently well between attacks, but often died suddenly.

Angina pectoris refers to a symptom complex and not a disease.[37, 72] However, its occurrence strongly suggests the presence of one of several specific underlying cardiac diseases. It always indicates the same basic physiologic disturbance, probably myocardial anoxia, whatever the underlying disease.

Definition

Angina pectoris is a clinical syndrome characterized by paroxysmal attacks of a distinctive pain or oppression usually situated retrosternally, radiating commonly to the precordium and left upper extremity and occasionally to other adjacent areas, precipitated by effort and often also by other factors, relieved rapidly by rest or nitrites, and sometimes complicated by sudden death.

Certain elements may be atypical but the occurrence of the pain or pressure with effort is an essential element of the syndrome. Of course the pain of angina pectoris may occur at rest, but if it does not also occur with effort or cannot be reproduced by bodily exertion the diagnosis of angina pectoris may be questioned. By this definition angina pectoris applies only to a grave clinical syndrome resulting from paroxysmal relative inadequacy of blood supply to the heart. The pain of angina pectoris is distinguished from the more prolonged and usually more severe chest pain that results from acute myocardial infarction (see p. 509).

CHARACTERISTICS OF THE PAIN OF ANGINA PECTORIS

Location of the Pain

The primary site of the pain during a paroxysm of angina pectoris is usually at or behind the middle or upper third of the sternum. The term retrosternal is preferable to describe this location because substernal is misunderstood by many to designate the region below the xiphoid process. The pain is usually centered at the level of the third or fourth rib. Sometimes the primary site of the pain is more extensive and includes most of the precordium. Pains that are localized to a discrete area near the cardiac apex or to the left supracardiac region are rarely manifestations of angina pectoris. Rarely the pain [illegible] localized entirely to the right anterior chest but otherwise has all the characteristics of angina pectoris.[46]

Sometimes a patient experiences paroxysms of pain which occur under the same circumstances as angina pectoris but are not located in the anterior chest. The pain may affect the left scapular or interscapular region, the left wrist or other parts of the upper extremities, the epigastrium, and rarely even distant structures such as a carious tooth [illegible] an inflamed

gallbladder or the like While such pain cannot properly be termed angina pectoris its paroxysmal occurrence with general bodily effort and its prompt cessation with rest or nitroglycerin suggest that it is due to the same cause and may have the same serious implications including the possibility of sudden death

Radiation of the Pain

While the pain may be localized exclusively to its site of origin behind the sternum frequently especially when it is severe it tends to radiate to the neck jaw and upper extremities In its most characteristic form the pain radiates across the precordium to the left shoulder and upper arm but it frequently extends as far as the elbow the wrist or the fingers The pain may reach the shoulder and upper arm and then skip to the wrist or it may radiate to the wrist and fingers alone without involving any other portion of the extremity Sometimes the pain clearly follows the distribution of the ulnar nerve along the ventral and medial surface of the hand and fingers but it may also pursue a more diffuse and irregular course

When severe the pain may spread to both shoulders or even to both upper extremities Not infrequently it radiates to the right shoulder arm or wrist without involvement of the left (contralateral radiation—Libman[70]) The pain may extend to the clavicle lower neck or throat jaw and teeth especially on the left side Rarely it extends upward to the face head and scalp Occasionally the pain of angina pectoris starts in the sternal region and radiates exclusively or predominantly toward the left scapular region Rarely it radiates downward to the epigastrium or either hypochondrium distributions observed more commonly with the pain of an acute myocardial infarction Sometimes the pain starts in the left wrist arm or shoulder and radiates toward the sternum (inverse radiation—Libman[70])

Character of the Pain

The pain of angina pectoris may be mild severe or excruciating but whatever its intensity it usually has a special or even characteristic quality It was this quality which led Heberden[68] to designate it by the term angina meaning strangling Other descriptive adjectives which have been used are constricting pressing boring or expanding The pain or discomfort has also been described as a sense of a band or vise around the chest or a feeling of tightness The pain is usually dull not sharp sticking or knifelike and constant not throbbing But the pain may be described as burning or as a heartburn which has led to diagnostic confusion with peptic ulcer or hiatus hernia Sometimes patients say definitely that there is no pain but only an oppression or a choking or a sense of a weight over the breast bone or a vague indescribable distress

When there is a sensation of strangling or choking extending from the sternum to the throat the discomfort is sometimes confused with respiratory difficulty and may be erroneously interpreted as dyspnea The patient may speak of difficulty in breathing due to pectoral oppression but careful questioning will differentiate this from true dyspnea Often the pain so resembles that of gaseous distention behind the sternum that the patient tries to belch in order to obtain relief

The pain often has an insistent quality which compels the patient to remain as quiet as possible even to hold his breath and if he has been running or walking to come promptly to rest This is a special feature of the pain of angina pectoris which is not necessarily related to its severity for in some of the most intense types of pain such as that associated with ureteral colic the patient often moves or thrashes about in preference to remaining quiet Frequently the sensation in the arms wrist or hands is described as a numbness or weakness less commonly as tingling Occasionally weakness or numbness of the wrists or arms occurs without concomitant retrosternal or precordial pain in patients who at other times present the more complete picture of angina pectoris

The skin and subcutaneous tissue including the muscles of the areas affected by pain may be tender during the attack and even in the intervals between the paroxysms but this is unusual Vasomotor and trophic disturbances of these hyperalgesic areas such as blanching and blister formation resembling herpes zoster have been described[9] Instances of localized sweating of the shoulder or arm in patients with angina pectoris have been recorded[88] Occasionally there are evidences of reflex stimulation of the left cervical sympathetic nerve such as hyperhidrosis of the left side of the face and dilatation of the left

pupil[93] But none of these manifestations is a common or characteristic feature

Certain psychic features often accompany the pain of angina pectoris[42, 16] The fear of immediate impending death termed angor animi is well known Latham[61] described it as a sensation of approaching dissolution This is a pathognomonic diagnostic feature of the attack although it is often absent Frequently patients are embarrassed to admit this fear Careful interrogation however often discloses that this was the dominant feature of the attack and the reason for their seeking medical care The angor animi during the actual paroxysm of angina pectoris should not be confused with the more vague fears of death which torment patients who discover the nature of their disease and learn that it is often terminated by sudden death

Duration and Relief of the Attack

The attack of angina pectoris usually lasts only a few minutes Riseman and Brown[100] found that 97 per cent of attacks of angina pectoris precipitated by exertion actually lasted less than three minutes but that the patient usually greatly overestimated the duration Such attacks generally subside after a minute or two if the patient rests immediately when the pain begins On the other hand attacks which occur with the patient at rest often persist for five to fifteen minutes or up to a half hour but rarely longer A mild residual local soreness may not disappear for hours When severe pain lasts for more than a half hour the presence of an acute coronary occlusion should be strongly suspected

The attacks of angina pectoris vary greatly in frequency Many patients having learned the maximum activity in which they can indulge without pain avoid pain completely for long periods by restricting exercise below the critical point Some patients suffer a single paroxysm of pain early in the day usually on walking after which they are able to carry on normal activity without symptoms Others have only occasional seizures at intervals of days weeks or months the intervals depending to some extent on avoidance of the factors which excite their attacks Still other patients less fortunate experience numerous seizures each day, often without apparent cause, or after some slight activity or even after simple essential physiologic functions

OTHER SYMPTOMS AND SIGNS

There is usually no dyspnea or respiratory distress but the patient may complain of being unable to breathe or he may actually hold his breath Burns[16] emphasized that If there be actual dyspnea present you may be sure the disease is either not syncope anginosa (i e angina pectoris) or that it is a complicated case with effusion in the chest ossification of the valves or asthma ' Belching is common and the passage of flatus occurs occasionally at the end of the attack, these symptoms are usually accompanied by a sense of relief Occasionally there is a desire to urinate after the attack and there may be polyuria Dizziness faintness and rarely syncope may occur (syncope anginosa—Gallavardin)[35, 77] but they are not intrinsic elements of the attack Palpitation is very unusual unless the attack is precipitated by some form of paroxysmal tachycardia

Physical Signs

It is important to emphasize that there are often no abnormal physical roentgenologic or electrocardiographic signs in patients suffering from angina pectoris When the underlying disease is syphilitic aortitis or calcific aortic stenosis the physical signs are those of the underlying disease (q v) In patients with an underlying coronary disease hypertension is frequent and there may be corresponding physical roentgenologic and electrocardiographic evidences of left ventricular enlargement (Chapter 5) In patients with previous myocardial infarction there may be electrocardiographic changes and physical and roentgenologic signs of myocardial disease or of ventricular aneurysm

The *blood pressure* between attacks may be normal but is often elevated Hypertension was present in 44 per cent of Riseman and Brown's[101] cases of angina pectoris During the attack there may be a rise in blood pressure[65] but as a rule the blood pressure does not change The cardiac output circulation time and venous pressure are normal Usually also the *pulse rate* is unaltered during the attack but this is variable A rise in blood pressure and a rapid cardiac rate are essential features in the unusual attacks of angina pectoris occurring in certain patients with aortic insufficiency (p 686)

The Electrocardiogram in Angina Pectoris

The electrocardiogram of patients subject

to angina pectoris may differ during the attacks from that taken in the free intervals. Ordinarily electrocardiographic studies are made while the patient is free from pain; then they are entirely normal in the large majority of patients in whom there is no previous clinical history of myocardial infarction or heart failure.[107] However, there may be abnormalities of the T and Q waves or of the QRS complexes such as frequently accompany advanced coronary disease (p. 433) with healed myocardial infarcts and fibrosis, or evidence of left ventricular hypertrophy if there is an underlying hypertension or aortic valvular disease.

During a spontaneous or induced attack of angina pectoris the electrocardiogram usually undergoes significant and often characteristic alterations which disappear with subsidence of the attack.[31, 1.5, 98] The essential electrocardiographic abnormalities are (1) a depression of the RS-T interval and (2) diminished amplitude and eventual inversion of the T waves. The RS-T depressions and T wave inversions occur in the standard or precordial leads but are most common and most striking ... the left precordial leads.

In cases of acute myocardial infarction an ... segment depression in lead I or lead III is ...aracteristically associated with a discordant ...vation of the ST segment in lead III or lead ... respectively, and Q waves are present. ...owever, an occasional instance of discord...t ST elevation and depression resembling ...ose seen after myocardial infarction has ...en reported in cases of angina pectoris ... 504).[14, 97, 103] ST *elevations* are most likely ... occur during an attack of angina pectoris ...hen transient coronary insufficiency is ...vere or is superimposed on healed myocar...al infarction.

The RS-T depressions and T wave changes ... angina pectoris are determined by the oc...urrence of ischemia without necrosis and by ...e localization to most of the subendocardial ...egion of the left ventricle. The subendo...ardial region is involved because it has the ...oorest blood supply and is subjected to the ...ighest pressure during ventricular contrac...ion. Myocardial anoxia due to ischemia re...ults in disturbances in depolarization and ...epolarization which are represented by RS-T ...eviations and T wave changes. When the ...ubendocardial region is hypoxic, the resulting ...hanges are reflected in electromotive forces (vectors), which are recorded in the electrocardiogram as a depressed RS-T wave. When the subepicardial region is generally involved by hypoxia, as in pericarditis, an elevated RS-T segment is recorded. When the entire transmural myocardium of one wall of the left ventricle is involved, as in myocardial infarction, there are RS-T elevations in the leads facing the affected wall and depressed RS-T segments in those facing away from that wall. When a substantial portion of the myocardium undergoes death of tissue (necrosis), negative cavity potentials are recorded on surface electrodes and Q waves appear. Hence Q waves are absent as a rule in cases of angina pectoris.

Only occasionally is it possible to make electrocardiograms during a spontaneous attack of angina pectoris. However, electrocardiographic studies during paroxysms precipitated intentionally by exercise, rebreathing air or breathing air of low oxygen tension have revealed abnormalities similar to those observed in spontaneous attacks (p. 467). These abnormalities may appear even when these procedures do not produce the pain itself.

The Ballistocardiogram

Ballistocardiographic abnormalities of varying degree have been described as a regular finding in patients with angina pectoris (p. 62).[12, 107] The findings include exaggerated respiratory variations in the ballistocardiographic complexes, decrease in amplitude and loss of regularity or definitiveness. The ballistocardiographic complexes are especially likely to deteriorate in patients with angina pectoris after cigarette smoking.[65, 2] None of these changes is characteristic for angina pectoris and at the present time they cannot be regarded as being of diagnostic value.

ETIOLOGY AND PATHOLOGY

A variety of factors may be concerned in producing angina pectoris. They may be classified as (1) precipitating factors such as exercise, (2) underlying factors such as coronary artery disease, (3) contributory factors such as anemia, and (4) predisposing factors such as age, sex, hypertension, etc.

PRECIPITATING CAUSES OF ANGINA PECTORIS

1. Bodily Exertion

Physical exercise is by far the most frequent and most significant precipitating cause of

angina pectoris Often a patient reports that while running for a bus on his way to work or while walking up a slight incline to the subway station he suddenly and for the first time in his life experienced a severe oppressive pain behind the sternum which caused him to stop and which so terrified him that he returned to his home From then on the pain recurred whenever he ran or walked uphill or even on the level beyond a limited distance

Walking outdoors is the commonest form of bodily exertion producing the attack Sometimes the patient suffers pain if he walks up the slightest incline but not at all on the level, or he experiences an attack when he walks rapidly for a half block or more but he can walk a mile or more without discomfort if he proceeds very slowly To avoid embarrassment some patients walk along slowly and stop repeatedly pretending to be window-shopping Because of this the Germans have designated angina pectoris as the *schaufenster krankheit* For some patients the amount of exercise which can be performed without pain is remarkably constant Riseman and Stern [102] using a stair climbing test observed that when repeated examinations were made of a given patient with angina pectoris approximately the same amount of exercise was necessary to induce an attack On the other hand some patients find that when an attack has been provoked by exertion they can after a brief rest period, resume activity without further pain even when the exercise exceeds that which originally induced the attack

The severity or amount of exertion does not seem to be the sole factor determining the precipitation of an attack Some patients suffer pain on walking two blocks on their way to work and then are able to perform rather heavy manual work at their occupation indoors without discomfort It is notable that many sufferers of angina pectoris can avoid an attack on walking if they eat lightly or if they wait several hours after a meal but experience a paroxysm if they walk only a brief distance soon after a heavy meal The element of hurry may be an important factor Walking in cold weather or against the wind may provoke pain, whereas similar or greater activity causes no symptoms when the weather is warm Finding that their attacks are more frequent in the winter than the summer, many patients spend their winters in Florida or other warm climates thereby greatly reducing or avoiding attacks of angina pectoris In one patient with angina pectoris on effort severe attacks of typical angina pectoris were induced whenever he turned and lay on his right side but not when he was supine or turned on his left side

The occurrence of angina pectoris following bodily exertion depends on the increased cardiac output and the increased work of the heart resulting from exercise These are associated with a greater demand for oxygen by way of the coronary circulation Normally this increased demand is satisfied by a diminished coronary arteriolar resistance [4] with consequent increase in the coronary blood flow [4] However, in patients with angina pectoris some underlying disease such as coronary sclerosis which renders the vessels rigid and narrow prevents this normal adaptation so that the increase in coronary blood flow is not proportionate to the increased demand of the heart When the exercise stops the coronary flow is again adequate and the attack of angina pectoris subsides Following this transient myocardial ischemia caused by exertion there may be an increase in coronary blood flow (reactive hyperemia) which permits the patient to perform, without pain the activity which had just induced an attack of angina pectoris

According to Raab[99] effort (and likewise emotion and cold) induces angina pectoris by causing an influx of catechol amines into the myocardium (adrenosympathogenic effect) These are thought to cause an exaggerated expenditure of oxygen by their specific chemical effect, independent of the work of the heart

2 Digestion

It has been noted that after a meal especially if considerable food is ingested, less effort is required to provoke an attack than ordinarily and electrocardiographic and ballistocardiographic changes are induced in patients with angina pectoris [8] Since digestion like exercise increases the work of the heart, the relative deficiency of coronary blood flow caused by exercise is exaggerated when the exertion follows a meal Occasionally a heavy meal by itself induces an attack even though the patient is at rest In the normal person digestion is associated with an increase in coronary blood flow proportionate to the increased needs of the heart, but this compensation is apparently ineffective in patients

suffering from angina pectoris because of some underlying coronary or cardiac disease Kuo and Joyner[40] related angina pectoris after meals to postprandial lipemia which reached its peak at the time of the pain I am skeptical of this attempted causal correlation

3 Cold

Like digestion exposure to cold enhances the probability of an attack of angina pectoris after an amount of exercise which ordinarily is not followed by pain Exposure to cold produces this effect by increasing the cardiac output and work of the heart and thereby augmenting the need for oxygen [33] Gilbert and his associates[37] observed a diminution in coronary blood flow in decerebrate dogs following stimulation of the nasal mucous membranes with ice water This effect was prevented by previous vagal section or the administration of atropine They interpreted the reduction in coronary flow as resulting from a reflex in which the trigeminal fibers were stimulated on the afferent arc and the vagi on the efferent thus producing coronary vasoconstriction Freedberg and his co-workers[33] reduced exercise tolerance and precipitated angina pectoris by the local application of ice to the hand presumably causing coronary vasoconstriction Reflex stimulation of epinephrine with consequent increase in cardiac work could also account for the angina pectoris [17] Exposure of the skin surface to cold may rarely induce an attack of angina pectoris even without the additional factor of exercise This is observed in patients who experience pain on retiring if the room or bed clothes are very cold or on stepping into a cold bath

4 Emotion

While intense emotional states may provoke in neurotic persons various forms of pain in the cardiac area which are distinct from angina pectoris they may also and often do cause definite attacks of angina pectoris whether or not there is an associated neurosis Vigorous discussion heated arguments the excitement of card playing or of watching a football game or a horse race grief and anger and a variety of petty annoyances may all induce an attack Frequently cardiac pain occurs during sexual intercourse and rarely the attack is fatal

Like other factors precipitating angina pectoris excitement is believed to act by increasing the work of the heart in subjects in whom because of some underlying disease the coronary blood flow cannot be proportionately augmented The increased work of the heart may be due in part to the hyper secretion of epinephrine which is associated with emotional states

5 Tachycardia

When severe tachycardia occurs in paroxysms (paroxysmal atrial fibrillation paroxysmal nodal tachycardia) it may induce an attack of angina pectoris in persons with a diminished coronary reserve Rapid heart rates above 160 per minute augment the oxygen consumption of the heart because for any given minute output the oxygen need of the heart is greater at rapid than at slow rates Coronary flow may be impaired with reduction in the duration of diastole In patients whose coronary reserve is limited the added myocardial needs for oxygen resulting from the tachycardia cannot be satisfied through the normal accommodative mechanisms Then a definite attack of angina pectoris may be induced

6 Hyperinsulinism and Hypoglycemia

In diabetic patients with severe coronary atherosclerosis excessive insulin dosage may induce attacks of angina pectoris or even of myocardial infarction (p 497) Similar paroxysms of cardiac pain and associated electrocardiographic changes have been induced by spontaneous episodes of hypoglycemia due to hyperinsulinism (p 1034) The angina pectoris has been attributed both to disturbed cardiac metabolism due to the hypoglycemia and to an increase in the production of epinephrine in response to the low blood sugar [7]

7 Other Precipitating Causes

Attacks of angina pectoris have been ascribed to the administration of thyroid extract especially in patients with myxedema (p 1020) It has been indicated that epinephrine as well as insulin may cause cardiac pain Occasionally tobacco appears to precipitate paroxysms in susceptible individuals [1, 4, illegible, 15, 118] Smoking may produce this effect by increasing the heart rate and elevating the blood pressure [104, illegible, 115]

Many attacks of angina pectoris occur without apparent cause or in the course of ordinary conversation especially if it is prolonged Straining at stool is sometimes responsible Preliminary to an attack of acute myocardial infarction angina pectoris may increase in frequency and occur with little or no provocation (p 508)

Occasionally attacks of angina pectoris are precipitated by the recumbent position especially at night and the patient is forced to walk about or sleep in the sitting position in order to obtain relief The term angina decubitus has been applied to this type of cardiac pain, which may be precipitated by increased cardiac output and work associated with recumbency However there has been considerable confusion about this term which has also been applied to the precordial oppression associated with paroxysmal nocturnal dyspnea and to the pain accompanying acute myocardial infarction

UNDERLYING CAUSES OF ANGINA PECTORIS

The above-mentioned precipitating factors induce attacks of angina pectoris only as a rule in subjects who are susceptible because of some underlying cardiac disease Since angina pectoris is a symptom complex which may be due to a variety of diseases a complete diagnosis should include not merely the term angina pectoris but also the underlying causative disease The basic conditions which are usually responsible for angina pectoris are (1) coronary atherosclerosis (2) syphilitic aortitis with coronary ostial stenosis, and (3) aortic stenosis Angina pectoris has been associated also with anemias especially pernicious anemia with hyperthyroidism and hypothyroidism tachycardias hypertension and mitral stenosis But it is uncertain whether these conditions are basic causes or merely contributing factors in the production of angina pectoris Not infrequently two or more of the above diseases are combined and may be jointly responsible

1 Coronary Atherosclerosis (See Chapter 16)

Coronary atherosclerosis is by far the commonest pathologic basis of angina pectoris Either coronary thrombosis or severe narrowing produces pain by interfering with the blood supply of the myocardium The pathologic findings and their correlation with angina pectoris are discussed below (p 456)

2 Syphilitic Aortitis with Coronary Ostial Stenosis

This is discussed in Chapter 35 The occurrence of angina pectoris is determined by severe narrowing or obliteration of the aortic mouths of the coronary arteries The increased myocardial need for blood, due to the enlarged size and work of the heart caused by an associated aortic insufficiency is a predisposing factor

3 Aortic Stenosis

Aortic stenosis of the severe variety, so called calcific aortic stenosis is often manifested clinically by angina pectoris (see p 700) Contrary to general belief, angina pectoris is a relatively more common symptom of calcific aortic stenosis than of aortic insufficiency The incidence and pathogenesis of cardiac pain is discussed elsewhere (p 701)

4 Aortic Insufficiency

Syphilitic aortic insufficiency is much more apt to be associated with angina pectoris than is rheumatic aortic insufficiency It is probable that angina pectoris is rarely due to the aortic insufficiency per se, even though the low diastolic pressure associated with that lesion would be expected to impair the coronary blood flow Compensatory factors tend to restore an adequate blood supply (p 685)

In cases of syphilitic aortic insufficiency, angina pectoris is due chiefly to the usually associated coronary ostial stenosis (p 894) In some cases of rheumatic aortic insufficiency with angina pectoris an associated coronary arteriosclerosis may be responsible for the cardiac pain In both rheumatic and syphilitic aortic insufficiency the valvular lesion may be a contributory but not primary cause due to the increased work of the heart and the need for a larger blood supply In some instances an aortic stenosis is overlooked and aortic insufficiency is diagnosed because of the presence of an aortic diastolic murmur In cases of angina pectoris in young individuals with rheumatic aortic insufficiency vasomotor or autonomic crises associated with a sharp increase in cardiac rate and blood pressure may be responsible for the pain (p 686)

5 Other Causative Diseases

Anemia Among the uncommon causes of angina pectoris anemia appears to have the clearest relationship to the production of this symptom [48] Angina pectoris has been reported most often with pernicious anemia,[111] but it has been observed also with secondary anemias of varied etiology [6] I have seen angina pectoris due to severe anemia disappear after the anemia was cured following resection of gastric and sigmoid neoplasms [2] Nevertheless even with pernicious anemia angina pectoris is uncommon, and in most series of cases has not been noted at all Willius and Giffen[1 2] found a history of angina pectoris in 43 or 2 7 per cent of 1560 patients

with pernicious anemia. On the other hand Pickering and Wayne[35] reported that 7 of 25 ambulatory patients with severe anemia complained of pain in the chest induced only by exercise and relieved by rest. They suggested that angina pectoris might occur more frequently in patients with severe anemia if they were not stopped by breathlessness, giddiness or intermittent claudication before they exerted themselves sufficiently to produce anginal pain.

In almost all of the reports of angina pectoris associated with anemia in which the hearts were examined at autopsy, severe coronary atherosclerosis or syphilitic ostial stenosis was found.[47] The case reported by Elliot[5] appears to be an exception, but since the heart weighed more than 600 gm. and the anemia was moderate (57 per cent Sahli), the causal relationship of the anemia to the angina pectoris may be questioned. The infrequency of angina pectoris in cases of anemia, the usual finding of advanced coronary atherosclerosis at autopsy when angina pectoris had occurred during life, and the usually prompt termination of the attacks when the hemoglobin is elevated by transfusions or other therapy indicate that anemia can predispose or contribute to attacks of angina pectoris, but only when there is an underlying disease which impairs the blood supply of the heart.

In the presence of severe anemia, diminished coronary resistance and increased coronary flow compensate for the lowered oxygen content of the blood. In the presence of coronary stenosis this increased blood flow is limited and may become inadequate during increased work of the heart.[18]

Arterial Hypoxemia. Angina pectoris is rarely encountered in cyanotic patients with chronic pulmonary disease or congenital heart disease (hypercyanotic angina), the pain occurring with intensification of cyanosis during activity.

Hyperthyroidism and Hypothyroidism. Rarely angina pectoris has occurred in association with hyperthyroidism[62] or with myxedema.[63] In hyperthyroidism the pain is likely to occur during recumbency (angina decubitus) and is relieved by iodine, thiouracil or subtotal thyroidectomy.[110] The frequency of hyperthyroidism and the rarity of associated angina pectoris suggest that hyperthyroidism is at most only a contributory causative factor. It appears likely that the primary underlying cause of angina pectoris in these cases is coronary artery disease.

Coronary atherosclerosis probably accounts also for the occasional instances of angina pectoris and hypothyroidism, for the latter is often associated with coronary artery disease (p. 1017). But despite the frequency of coronary atherosclerosis, angina pectoris is uncommon in myxedema because the low metabolic rate results in a reduced myocardial requirement for blood. The relationship of myxedema to angina pectoris is discussed in the chapter on the former (p. 1020). Both the appearance and the relief of angina pectoris in myxedema have been attributed to thyroid extract (p. 1020).

Mitral Stenosis. Angina pectoris has been noted occasionally in cases of mitral stenosis.[6] Stuckey[114] reported 34 cases (8.5 per cent) of angina pectoris of effort among 400 patients with mitral stenosis and correlated the angina with a low cardiac output. Mechanical factors, such as compression of the left coronary artery between an enlarged left atrium and a dilated pulmonary artery, have been invoked to account for the angina pectoris. But considering the frequent occurrence of mitral stenosis and of angina pectoris as separate entities, the comparatively rare coexistence of the two conditions in the same patient must be explained as accidental, not causal, the former being usually due to rheumatic infection and the latter to independent coronary disease.

Angina pectoris has also been reported in cases of Friedreich's ataxia[29, 112] and other diseases occasionally associated with myocardial damage and cardiac hypertrophy.

CONTRIBUTING FACTORS

These are conditions which favor the occurrence of angina pectoris in subjects who are already susceptible because of coronary disease, syphilitic aortitis with coronary ostial stenosis or aortic valvular disease. The contributing factors, unlike the basic underlying causes, are by themselves incapable of producing angina pectoris and, unlike the precipitating factors, do not immediately initiate the individual attacks. These distinctions have not been and sometimes cannot be sharply drawn. Hyperthyroidism and anemia are two factors which, as I have indicated, may be properly considered as contributory factors in

the production of angina pectoris although they have also been reported as primary underlying causes

Diabetes predisposes to angina pectoris because of its relation to coronary atherosclerosis (p 425)

Hypertension is often found in patients with angina pectoris but usually the latter may be properly attributed to associated coronary disease *Hypertension is especially frequent in women with angina pectoris* (90 per cent or more in some series)[illegible], [21] Davis and Klainer[21] found an extreme degree of coronary disease involving two or more major arteries, in 95 per cent of non hypertensive patients with angina pectoris Similar severe coronary disease was observed in only 39 per cent of hypertensive patients with angina pectoris They concluded that if hypertension is present angina pectoris occurs frequently, even in the absence of severe coronary disease But in subjects with normal pressure angina pectoris is almost always dependent on the presence of severe coronary disease In other words severe coronary disease may by itself result in angina pectoris, if hypertension is associated angina pectoris may occur even when the coronary disease is of moderate degree The hypertension increases the work of the heart and leads to cardiac hypertrophy Both of these changes increase the requirements of the heart for oxygen In this way hypertension enhances the likelihood of angina pectoris if there is already some disturbance in cardiac circulation Similarly cardiac hypertrophy from any cause may increase the incidence of angina pectoris *Hypertension contributes indirectly to the occurrence of angina pectoris* by favoring the development of atherosclerosis of the coronary arteries[55] (p 428)

Familial Xanthomatosis and Hypercholesterolemia (p 1041) are frequently associated with angina pectoris because of the frequent and early occurrence of advanced atherosclerosis in these conditions (p 425)

Pheochromocytoma

Angina pectoris is occasionally observed in the rare cases of acute paroxysmal hypertension due to pheochromocytoma (paraganglioma) of the adrenal medulla (p 1025)

Disease of the Biliary and Gastrointestinal Tracts

The causal relationship of diseases of the gastrointestinal and especially of the biliary tract to angina pectoris has been stressed in recent years Chronic cholecystitis and cholelithiasis, duodenal ulcer, diaphragmatic hernia and organic and functional disturbances of the esophagus have been documented as causes of angina pectoris The symptoms of indigestion often associated with the attacks and their relief with eructation and the passage of flatus as the attack abates have suggested that reflexes from the esophagus stomach duodenum or colon could produce angina pectoris, perhaps by causing vagal vasoconstriction of the coronary arteries

This concept was supported by experimental observations that distention of the stomach with balloons decreased the coronary blood flow [3, 46] and that a similar procedure induced angina pectoris in humans These effects were prevented by previous section of the vagi or administration of atropine Electrocardiographic changes were observed in humans during experimental distention of the gallbladder[30] but not during manipulations of the biliary tract in operations on the gallbladder [31a] Recently experimental distention of the gallbladder in normal dogs caused no significant electrocardiographic changes but the same procedure produced marked RST segment deviation and increased height of T waves in dogs which had had a previous experimental coronary artery occlusion [60] Following a theory postulated by Verdon [117] the Jacksons[53] submitted experimental and clinical evidence that angina pectoris was caused by acute spasmodic uncoordinated contractions of the esophagus and stomach due to local gas traps and gaseous distention *The theory that disease of the biliary and gastrointestinal tract associated with the distention of these hollow viscera and vagal reflex coronary vasoconstriction can produce angina pectoris must be distinguished from the fact that normal digestion may precipitate angina pectoris in susceptible subjects* The latter can be explained adequately by the increased work of the heart during digestion independent of reflex action

The available data suggest that *disease of the biliary tract* is more common in patients who die of coronary disease (and angina pectoris) than in control groups of patients [11] Yet there is no proof that coronary disease causes gallbladder disease or vice versa or that a common etiologic factor is responsible for the association [118] Occasional cases have

been recorded in which anginal attacks and electrocardiographic abnormalities disappeared after cholecystectomy [28] It is probable that in these cases the diseased gall bladder acted only as a contributory cause of pain in the presence of underlying coronary or aortic disease In many cases of so-called angina pectoris due to gallbladder disease there is a failure to distinguish carefully between the pain radiation of cholelithiasis and cholecystitis and angina pectoris, as a rule the two can be clearly distinguished Occasionally common afferent pathways cause the referred pain of biliary disease to simulate that of angina pectoris or vice versa

Peptic ulcer is more often associated with coronary disease and angina pectoris than is generally recognized but the association may be no more frequent than a to be anticipated from the high incidence of the individual diseases Sometimes the anginal syndrome appears and recurs simultaneously with the activation of an old peptic ulcer and disappears when the ulcer is successfully treated [8] A bleeding ulcer[66] may precipitate angina pectoris in patients with coronary disease because of the induced anemia (p 1046)

Hiatus (paraesophageal) hernia has occasionally caused symptoms resembling angina pectoris [11] Careful analysis of the character location radiation and precipitating causes of the pain usually discloses distinctive differences from that of angina pectoris Resemblances may be due to the transmission of pain impulses from the esophagus over cord segments which are similar to those carrying pain impulses from the heart Occasionally hiatus hernia causes chronic esophageal or gastric bleeding and a severe secondary anemia in such cases the anemia may contribute definitely to the development of angina pectoris [9]

PREDISPOSING FACTORS

Age and Sex

At least 90 to 95 per cent of patients with angina pectoris are beyond the age of 40 and more than 70 per cent are beyond the age of 50 Angina pectoris in young persons (below the age of 30) has however been recorded [35] Eppinger and Levine [8] found the average age of onset of angina pectoris to be 56 for males and 58 for females and the range between 35 and 70 years

Angina pectoris occurs predominantly in males the ratio varying from 3 to 1 to 6 to 1 in different series [illegible] [31] As a rule angina pectoris occurs in females only when there is an associated diabetes or hypertension [115] but the number of exceptions appears to be increasing in my experience

Occupation Social and Economic Status and Race

These are discussed in connection with the basic diseases responsible for angina pectoris

Heredity (see under Coronary Atherosclerosis p 416)

Constitution and Temperament (see under Coronary Atherosclerosis p 416)

PATHOGENESIS

Although a variety of explanations have been offered for the mechanism of angina pectoris and although there is still some difference of opinion as to its exact pathogenesis the most widely accepted theory at the present time is that the pain and associated phenomena result from myocardial anoxia induced by coronary insufficiency [87]

Coronary Insufficiency and Myocardial Anoxia

Whenever the coronary blood flow quantitatively or qualitatively fails to keep pace with the myocardial needs coronary insufficiency is said to be present [15] Coronary insufficiency is thus defined as a disproportion between the blood supply and the blood requirements of the myocardium Coronary insufficiency is here employed as a physiological term and should not be confused with recent usage of this term to denote a purportedly distinctive clinical syndrome The latter is discussed below (p 461) Coronary insufficiency may be due to a diminution in coronary inflow an increase in the size and work of the heart a deficiency in the oxygen content of the blood or a combination of these The following are more specific causes of coronary insufficiency (1) coronary occlusion recent or old (2) coronary atherosclerosis with extreme narrowing (3) coronary ostial narrowing or occlusion due to syphilitic aortitis (4) aortic stenosis (5) conditions associated with a reduction in aortic blood pressure e g massive pulmonary embolism and other shock states (6) conditions associated with a reduction in oxygen content of the blood e g anemia arterial hypoxemia due to pulmonary or congenital

heart disease, carbon monoxide poison or low atmospheric oxygen tension (7) drugs e g epinephrine administered therapeutically or spontaneous epinephrinemia in cases of pheochromocytoma (p 1025)

Confusion has resulted from an attempt to limit the term coronary insufficiency to functional deficiencies in the coronary circulation thus excluding mechanical obstructions of the coronary artery i e coronary occlusion Angina pectoris which is one of the most striking symptoms of coronary insufficiency is due more often to old coronary occlusion than to any other cause Angina pectoris and coronary insufficiency are not synonymous Coronary insufficiency is a disturbance which under special circumstances may produce angina pectoris and under others myocardial necrosis or infarction or it may be documented only by electrocardiographic abnormalities unassociated with pain Coronary insufficiency necessarily denotes myocardial anoxia or hypoxia This should be emphasized because it is the myocardial anoxia which accounts for the cardiac pain of angina pectoris the necrosis of muscle and consequent fever leukocytosis etc in coronary thrombosis and the electrocardiographic changes associated with either coronary thrombosis or angina pectoris

Normally the coronary circulation is adequate for the myocardial needs at any given moment A wide range exists between the coronary flow under basal conditions and the larger flow when myocardial requirements are maximal This range may be termed the *coronary reserve* Under physiologic conditions the coronary flow can be augmented by certain compensatory adjustments which reduce the coronary resistance by dilating the coronary vessels Under pathologic conditions the development of a collateral circulation also helps to maintain an adequate myocardial blood supply but this may not be adequate under all circumstances When the coronary blood bed is attenuated by narrowing or obliteration of vessels or when the myocardial needs are increased by cardiac hypertrophy or valvular disease the range between basal coronary blood flow and maximal coronary blood flow becomes narrowed There may then be said to be a diminution in coronary reserve

When the coronary reserve is diminished to the point where the flow is adequate only for ordinary needs, any sudden further depletion of the blood supply or increase in myocardial demands may result in coronary insufficiency and myocardial hypoxia The coronary blood flow may be reduced by a fresh coronary occlusion by an acute hemorrhage or by a sharp reduction in blood pressure following massive pulmonary embolism acute pancreatitis, etc , or the myocardial blood demand may be augmented by bodily exertion excitement digestion cooling of the surface of the body or any other factor which exaggerates the work of the heart If the coronary insufficiency thus produced is sufficiently severe and prolonged the resultant myocardial anoxia may be followed by necrosis of an area of heart muscle (myocardial infarction) When however the coronary insufficiency is less severe and especially if it is transient e g with physical exertion or excitement, the resultant myocardial anoxia excites only certain temporary metabolic disturbances in the muscle which are completely or almost completely reversible Such episodes of acute transient coronary insufficiency are believed to account for the appearance of angina pectoris

According to this explanation the pain of angina pectoris and that of acute coronary occlusion (with myocardial infarction) are both due to acute coronary insufficiency the difference in duration and severity of the pain depending on differences in degree and duration of the coronary insufficiency That the pain of acute myocardial infarction and that of angina pectoris arise similarly from coronary insufficiency (with myocardial anoxia) is supported by (1) clinical resemblance (2) electrocardiographic evidences of myocardial impairment in spontaneous and induced attacks of angina pectoris (see below) and (3) the occasional discovery of foci of necrosis in the hearts of patients who died shortly after having suffered from attacks of angina pectoris[14]

Pathologic Basis of Coronary Insufficiency and Angina Pectoris

That the mechanism of angina pectoris was in some way related to coronary artery disease has been known since Jenner Black[4] Parry Burns[16] and subsequently others repeatedly found thickening calcification or obstruction in the coronary arteries of patients who had suffered from this symptom complex The relationship was obscured by the

frequency with which coronary atherosclerosis was found in individuals who had not suffered from angina pectoris during life and by the occasional occurrence of angina pectoris in individuals whose hearts disclosed normal coronary arteries at autopsy On the other hand Sternberg[114] invariably observed coronary artery disease at autopsy in cases of angina pectoris Braun[16] reported a series of 127 cases of angina pectoris in all of which there was severe coronary atherosclerosis Usually the narrowing was so pronounced that there was scarcely any lumen

Most of these discrepancies or uncertainties have been adequately clarified by the theory that angina pectoris is the result of myocardial anoxia due to a transient acute coronary insufficiency[17] That only a small percentage of cases of coronary sclerosis are associated with angina pectoris is due to the fact that significant interference with the blood supply to an area of myocardium (i e coronary insufficiency) can occur only when the vascular lumen is narrowed extremely or entirely obstructed Mann and associates[78] demonstrated that the internal diameter of a vessel could be decreased to one half its original diameter over a distance of 8 to 10 mm without reducing its blood flow significantly Even with complete obstruction of a vessel its area of supply may receive an adequate amount of blood through collateral anastomosing vessels provided that the obstruction became complete only after a long interval of slowly progressive arterial narrowing This is indicated by the studies of Blumgart Schlesinger and Davis[8] who demonstrated that angina pectoris occurred as a rule after two and exceptionally after one major coronary artery was occluded and the remaining major branches were severely narrowed Blumgart Schlesinger and Zoll[7] demonstrated that in cases of old coronary occlusion without a history of angina pectoris there was an average of 1 4 occlusions per heart whereas in cases of old coronary occlusion with a history of angina pectoris there was an average of 3 5 occlusions per heart These findings also support the probability that the onset of the first paroxysm of angina pectoris is due to an acute coronary occlusion without infarction or to an intimal hemorrhage with sudden marked increase in narrowing of the lumen rather than to gradual progressive narrowing Otherwise it is difficult to understand why a man who daily takes the same walk to his bus or train suddenly finds himself incapable of doing so without pain Frequently there is no pain until the occurrence of a clinical attack of acute coronary occlusion with infarction angina pectoris appears following convalescence and resumption of activity

The opposite circumstance that angina pectoris was sometimes observed in the absence of significant coronary artery lesions may be accounted for in several ways Recent improvements in the postmortem study of the coronary arteries have demonstrated that former investigators often overlooked severe coronary artery disease especially coronary artery occlusions Thus my own investigations with the late Dr Louis Gross and those of my associates[61] like those of Saphir et al[106] and more recently of Blumgart et al[6,7,124] have shown that multiple coronary occlusions are much more common than formerly believed and that the right coronary artery and left circumflex artery are occluded almost as often as the left anterior descending whereas older observers usually discovered occlusions only in the latter Sometimes also in coronary vessels which appeared patent throughout their course extreme narrowing or obliteration of the ostia due to syphilitic aortitis was formerly overlooked Furthermore it is now recognized that coronary insufficiency and angina pectoris may occur in the presence of normal coronary arteries as a result of other cardiovascular or valvular diseases which disturb circulatory dynamics so as to diminish the coronary blood flow or increase the myocardial requirement These other causative diseases such as aortic stenosis have been listed above

Evidence for the Theory of Myocardial Anoxia *(Secondary to Coronary Insufficiency)*

1 The pathologic data presented above are the strongest evidence for the belief that coronary insufficiency and resulting myocardial anoxia account for angina pectoris In most instances there is an actual mechanical interference with a major portion of the blood supply to the myocardium In the remaining cases there are pathologic abnormalities in the valves the heart or the circulation which lead to a diminution in coronary blood flow and an augmentation of myocardial blood

demand or an impoverishment of the oxygen content of the blood

2 That obstruction of the coronary circulation may cause pain was indicated by the experimental observations of Sutton and Lueth[116] on unanesthetized dogs These authors caused the animals to become restless and tachypneic and to behave as if they were in pain whenever they temporarily ligated a large coronary artery Furthermore temporary clamping of a coronary artery in experimental animals results in reversible electrocardiographic changes[30, 115] resembling those seen during attacks of angina pectoris in humans

3 Additional support is found in the similarity in character location and distribution of the pain in acute coronary occlusion and that of angina pectoris That the pain of the former is due to myocardial anoxia is readily accepted because of the pathologic finding of myocardial necrosis It is therefore probable that myocardial anoxia of less intense degree and briefer duration may be invoked to explain the similar but more transient pain of angina pectoris The observation of Buchner[14] that careful study will demonstrate focal necrosis of the myocardium in patients who had suffered from attacks of angina pectoris just before death indicates that the myocardial anoxia of angina pectoris may produce anatomic as well as functional alterations

4 More direct evidence that the pain of angina pectoris is due to myocardial anoxia was supplied by the experiments of Rothschild and Kissin[106] and of Dietrich and Schwiegk[33] These observers induced generalized anoxemia in patients who presented a history of angina pectoris or other evidence of coronary disease by having them rebreathe low oxygen mixtures or by placing them in a chamber with low oxygen tension In a high percentage of these cases an attack of angina pectoris was induced during the experiment and electrocardiographic alterations similar to those which occur when patients suffer spontaneous attacks of angina pectoris were observed With the administration of normal concentrations of oxygen, the pain disappeared and the electrocardiogram reverted to its previous appearance

5 Cases in which severe anemia either by itself or in association with underlying coronary disease provokes attacks of angina pectoris also support the theory that the latter is due to myocardial anoxia For the essential abnormality in anemia is reduction in the oxygen carrying power of the blood In at least some of these cases it has been shown that when the anemia is relieved by transfusion the attacks of pain cease promptly[5] It has also been shown that both in experimental and clinical carbon monoxide poisoning[1] in which the oxygen combination with hemoglobin is replaced by carbon monoxide electrocardiographic changes and myocardial necrosis occur similar to those observed in human cases of angina pectoris[illegible] Similarly in animals and humans exposed to high altitudes (above 5000 meters) corresponding to an oxygen saturation of the atmosphere of 80 per cent or less electrocardiographic changes occur which are similar to those seen with spontaneous or induced attacks of angina pectoris These observations indicate that it is the deficiency in oxygen which is the essential cause of angina pectoris

6 The pathogenesis of the pain in intermittent claudication of the lower extremities has been used by analogy to support the anoxic theory of angina pectoris In experiments simulating intermittent claudication MacWilliam and Webster[illegible] and Lewis Pickering and Rothschild,[66] showed that interruption of the arterial flow in the arm gave no pain if the arm was at rest However, if the arterial flow was reduced and the hand and forearm exercised pain occurred and was located not in the course of the artery but in the working muscle distal to the obstruction The observations were interpreted to indicate that the oxygen requirement of the *resting* muscle was satisfied even when the arterial flow was reduced, but that when the muscle was exercised the greater oxygen need of the active muscle could not be supplied with consequent appearance of pain By analogy, a patient with diminished coronary blood flow may have no pain at rest but suffers an attack of angina pectoris when the work of the heart is increased during bodily exertion

7 The theory of myocardial anoxia is compatible with the frequency of sudden death in patients with angina pectoris for it is generally believed that sudden death is usually due to ventricular fibrillation and the latter is especially favored by an oxygen deficiency of the myocardium[109]

Theory of Coronary Spasm It has been pro

posed that coronary arterial spasm is responsible for the actual attack of angina pectoris, whether or not there is underlying organic disease of the vessels[61, 84] The hypothesis of coronary spasm was invoked particularly to explain cases of angina pectoris and sudden death in which significant coronary lesions were not found at necropsy[6] It also appeared to account for attacks of angina pectoris occurring at rest especially those unassociated with tachycardia or an elevation in blood pressure or without any other apparent reason for diminished coronary blood flow or increased cardiac work Coronary spasm could also explain the sudden occurrence and disappearance of the paroxysm its reversible nature and its relief by vasodilator drugs such as the nitrites

Except for such rare unexplained occurrences as the complete disappearance of the radial pulse during an attack of angina pectoris[75] there is no significant positive evidence for the theory of coronary spasm since such spasm has never been observed Experimental evidence that distention of the esophagus or stomach may cause reflex vagal coronary vasoconstriction has been mentioned Prolonged vagal stimulation or administration of acetylcholine was reported to have produced severe coronary artery degeneration and thrombosis[24] These observations have been used to support a concept of coronary artery spasm due to vagal vasoconstriction Various specific objections to this hypothesis have been raised by Goldenberg and Rothberger[40] on the basis of their experimental studies

SITE OF ORIGIN AND CAUSE OF PAIN

It is probable that the pain of angina pectoris arises in the heart muscle although the aorta and the coronary arteries have also been implicated as the site of its origin

Sutton and Lueth[116] produced pain as manifested by restlessness and distress in unanesthetized dogs by temporary partial or complete constriction of a large coronary artery The pain was associated with rigidity and limping of the left foreleg signs which were interpreted as corresponding to the referred pain and muscle spasm in the left arm of humans with angina pectoris Whereas Sutton and Lueth concluded that the pain resulted from a diminished coronary flow to the myocardium other observers have suggested that the cause of pain following experimental coronary narrowing or occlusion was a direct stimulation of the nerve plexus surrounding the artery[88] or a distention of the coronary artery proximal to the obstruction associated with increased pressure in that segment[41] But Wiggers and Cotton[1] demonstrated that occlusion had no effect on the proximal coronary pressure and Sutton and Lueth[116] excluded coronary distention or pressure on the pericoronary nerves by producing pain in their dogs when the mouth of a coronary artery was plugged by a brass rod with a knob at its end These observations as well as the similar experimental observations of White Garry and Atkins[10] and of Shambaugh[109] and the data presented above to support the theory of myocardial anoxia lead to the conclusion that the pain associated with angina pectoris arises in the heart muscle and not in the aorta or coronary arteries

The exact *stimulus* which gives rise to pain is uncertain but it is most generally believed that it is a chemical one related directly or indirectly to the lack of oxygen in the muscle tissue However it is still undetermined whether the oxygen lack directly or whether the accumulation of metabolic products which are incompletely washed away by the coronary blood actually provides the stimulus for pain[74, 88, 46] In summarizing the various experimental and clinical observations on the pain of angina pectoris Katz[55] concluded that the stimulus responsible for pain is one or more acid metabolites such as lactic pyruvic or phosphoric acid or some non acid metabolite such as histamine phosphocreatine *adenosine or potassium which is formed* during cardiac contraction and accumulates in excessive amounts only when there is a relative oxygen deficiency

NERVOUS PATHWAY OF PAIN IN ANGINA PECTORIS

Recent anatomic and experimental studies and the effects of nerve block or excision in humans have added greatly to our still incomplete knowledge of the pathway by which pain is conducted from the heart A detailed discussion is presented in the monographs of White and Smithwick[11] and of Miller[82] The stimulus for the pain arises in the heart muscle itself but the pain fibers are located in a rich plexus in the adventitia of the coronary ar

teries and in the periarterial subepicardial tissue[49] Sutton and Lueth[118] and Katz, Mayne and Weinstein[58] demonstrated that after destruction of the pericoronary nerves by excision or painting with alcohol pain no longer appeared following experimental coronary occlusion in dogs

The pain impulses apparently are conducted only through the sympathetic nerves, although afferent as well as motor fibers are also present in the vagus. After reaching the periarterial nerves the pain impulses traverse the superficial and deep cardiac plexuses and then course through thoracic cardiac nerves to the upper four or five thoracic (paravertebral) sympathetic ganglia Other pain fibers from the cardiac plexuses extend in the superior middle and lower cervical cardiac nerves to the corresponding cervical sympathetic ganglia and then descend again to the upper four or five thoracic sympathetic ganglia

Having thus reached the upper thoracic sympathetic ganglia directly or indirectly the pain impulses enter the cord by way of the white rami communicantes which join these ganglia to the upper four or five thoracic spinal nerves As a practical basis for understanding the rationale of nerve block in the treatment of severe, protracted angina pectoris it should be recognized that all the nerve impulses arising in the heart and traversing the sympathetic nerves eventually converge in the upper four or five thoracic sympathetic ganglia and spinal thoracic nerves White Garry and Atkins[1] demonstrated that the pain caused by constriction of the anterior descending coronary artery in dogs could still be elicited after both vagi in the neck were cut or after the stellate ganglia and inferior portion of the sympathetic chains were resected However coronary constriction failed to result in pain following resection of the stellate and upper four pairs of thoracic sympathetic ganglia or resection of the upper five pairs of the thoracic posterior spinal roots These findings are in harmony with the observation that anesthesia of the above mentioned ganglia effectively relieves pain in humans with angina pectoris However the persistence of some of the pain in a minority of patients suggests that in these patients afferent nerve fibers carrying pain impulses from the heart may travel through the vagus and phrenic nerves[34]

THE PHYSIOLOGIC BASIS FOR THE PERCEPTION AND RADIATION OF ANGINAL PAIN

The pain arising in the heart eventually reaches the thalamic regions of the brain probably ascending in the spinothalamic tract of the cord It is believed that since the pain fibers from the heart join the spinal nerves before entering the cord the same segments of the cord (D1–D5) receive visceral pain sensations from the heart and somatic pain sensations from the corresponding areas of the body surface known as dermatomes According to the Mackenzie[73] theory of referred pain the pain impulses arising in internal organs are not perceived as originating in these organs but appear to arrive from the corresponding peripheral dermatomes which send afferent nerves to the same segments of the cord as the internal organ[73, 42] With respect to the heart, the corresponding surface area, chiefly D1–D4, includes the precordium the medial half of the anterior surface of the arm, the forearm and fifth finger However some of the pain arising in the heart may not be referred but may reach the thalamus directly and be perceived as arising in the heart This may account for the primary oppressive discomfort localized to the retrosternal region

The reason for the variations in the occurrence and radiation of the pain in patients with apparently similar coronary lesions is still unclear Undoubtedly these variations are due in part to individual differences in sensitivity to pain in general

The pain of angina pectoris which arises in the heart differs in quality from pains of somatic origin which are localized to similar areas of the chest wall and arms Pain is believed to be transmitted by slow conducting medullated (B group) and non medullated (C group) fibers[11] Differences in quality of pain may be determined by various possible combinations of B and C fibers which are simultaneously excited, the duller and more prolonged visceral pain representing a greater preponderance of excited non medullated C fibers The pain fibers running directly from the heart to the central nervous system may produce a special modality of pain, which differs from that perceived through somatic afferent radiations

Some of the distinctive features of the pain of angina pectoris and of associated phenomena are due to vagal and sympathetic efferent

and somatic motor reflexes which are initiated by the afferent pain impulses Reflex muscular spasm may account at least in part for the shoulder pain and weakness of the upper extremities as well as for the sense of compression and fixation of the chest wall The sense of strangling may in at least some cases be due to reflex spasm of the pharyngeal muscles Sweating and other vasomotor disturbances and gastrointestinal symptoms associated with angina pectoris may be due to vagal and sympathetic reflexes

ANGINA PECTORIS AND CONGESTIVE HEART FAILURE

There is no intimate relationship between angina pectoris and congestive heart failure In fact it is a common observation that patients with angina pectoris sometimes lose their pain when congestive heart failure develops Usually the manifestations of congestive heart failure especially dyspnea by considerably curtailing the patient s activities eliminate the chief precipitating factor of angina pectoris namely physical exertion On the other hand angina pectoris may persist or become intensified after the onset of heart failure This is likely to occur if the heart failure was induced by a coronary occlusion with myocardial infarction

So-called angina pectoris has been observed during attacks of paroxysmal nocturnal dyspnea (cardiac asthma) due to left ventricular failure[67] Some of these attacks of pain represent an acute coronary occlusion In other instances there is precordial discomfort due to acute dyspnea which however may not properly be termed angina pectoris Aside from these exceptions there are true instances of angina pectoris occurring at night in patients at rest and recumbent with or without concomitant paroxysmal dyspnea Acute left ventricular dilatation elevation of blood pressure tachycardia and consequent increased work of the heart have all been invoked to explain the occurrence of this angina pectoris so-called angina decubitus But the actual cause remains obscure

ANGINA PECTORIS AND INTERMITTENT CLAUDICATION

Since angina pectoris and intermittent claudication are both due to atherosclerosis and consequent arterial narrowing and occlusion both clinical syndromes may occur in the same individual However atherosclerosis in the coronary arteries and in the peripheral extremities are not usually equally extensive or equally complicated by narrowing or occlusion Furthermore limitation of activity by angina pectoris may prevent the clinical manifestation of intermittent claudication or vice versa McDonald[81] found that among 50 patients presenting with angina pectoris intermittent claudication was present in 4 and oscillographic evidence of occlusive arterial disease in an additional 8 Conversely among 79 patients presenting with intermittent claudication angina pectoris was manifested in 23 and electrocardiographic evidence suggesting ischemic heart disease but no angina pectoris in an additional 8

ACUTE CORONARY INSUFFICIENCY

The term acute coronary insufficiency is employed here to denote what is purported to be a distinct clinical pathologic entity[77, 78] It is presented not in concurrence with this concept but in acknowledgment of the widespread usage of this term Coronary insufficiency as a clinical entity is distinguished from coronary insufficiency a physiologic disturbance denoting an inadequacy of coronary blood flow for myocardial needs

The difficulty which many physicians experience in making an exact clinical pathologic diagnosis of a coronary episode based only on the clinical history examination and electrocardiogram accounts for much of the popularity of the diagnosis acute coronary insufficiency The ill defined diagnosis coronary insufficiency appears to solve this difficulty by providing a convenient term of diagnostic avoidance or evasion like the term rheumatism of old or the term collagen disease of more recent vintage the recourse of the physician who cannot make or will not attempt to make a more exact diagnosis of the underlying pathology There is danger that the diagnosis coronary insufficiency may lead to the false assumption that we have defined the nature of the disturbance by giving it a euphonious name when we really do not know exactly what has occurred

Definition of Terms

Unfortunately coronary insufficiency as a clinical pathologic concept has been variously defined[67, 78, 3, 77, 72, 79] In 1936 Levy and Bruenn[67] described under the heading acute fatal coronary insufficiency a series of

hospitalized patients with coronary heart disease who died suddenly but who at postmortem examination were found to have coronary atherosclerosis without fresh coronary occlusion In 1939 Büchner[15] described all forms of coronary attacks under the inclusive heading coronary insufficiency (*die Koronarinsuffizienz*[15]), but incorporated therein coronary occlusion and myocardial infarction as well as other severe and mild forms of coronary attacks without actual coronary occlusion In 1939 also Friedberg and Horn[34] described 37 cases of acute myocardial infarction without associated fresh occlusions of the coronary arteries chiefly in cases of pulmonary embolism and calcific aortic stenosis but also in severe acute anemia following operation and following a cerebral accident in patients with malignant hypertension Usually there were disseminated foci of necrosis or myomalacia involving chiefly the papillary muscles and subendocardial layers of the left ventricle The myocardial damage was attributed to intense coronary insufficiency due in part to the underlying coronary atherosclerotic narrowing and in part to the dynamics of the causative disease such as pulmonary embolism or aortic stenosis or the shock or anoxia of an operation severe acute anemia or a cerebral accident The term coronary insufficiency applied to the physiologic disturbance of an inadequate coronary blood supply but no clinical pathologic entity was implied

Chiefly on the basis of the electrocardiographic changes in the above cases of Friedberg and Horn[34] Master Gubner et al[78] attempted to differentiate acute coronary insufficiency (without coronary occlusion but with myocardial infarction) from coronary occlusion Subsequently Master and associates have been active in describing and popularizing acute coronary insufficiency as a complete entity with its own definite predisposing and precipitating factors its peculiar pathology and physiology characteristic electrocardiographic changes and requirements of distinctive treatment A careful review of their reports has not convinced me of the validity of this concept or of the justification of giving a new and clinical definition to a well established physiologic term Their cases form a motley group which are best classified clinically as angina pectoris (more or less severe or prolonged) or as myocardial infarction

Clinical Features

Acute coronary insufficiency is a diagnosis applied to a variegated group of attacks in which cardiac pain is more severe or more prolonged (more than 15 to 30 minutes) than in simple episodes of angina pectoris but without the typical signs or characteristic electrocardiographic pattern of myocardial infarction According to these criteria "acute coronary insufficiency is identical with 'coronary failure, an additional unnecessary term for cardiac pain intermediate between angina pectoris and myocardial infarct [13]

But Master and associates employ the term acute coronary insufficiency to include also patients who experience fever leukocytosis and accelerated erythrocyte sedimentation rate, and in whom myocardial necrosis is found at autopsy provided that the necrosis is not due to acute coronary occlusion Their assumption that there is no coronary occlusion is based on the electrocardiographic findings, which are not those of transmural (through and through) infarction

Acute coronary insufficiency is also applied to a group of cases in which cardiac pain may or may not be present but in which there are predisposing or precipitating factors, such as pulmonary embolism shock, hemorrhage or tachycardia and electrocardiographic changes indicating coronary insufficiency [79]

Electrocardiographic Changes

The diagnosis of "acute coronary insufficiency" is based frequently on the electrocardiographic finding of RS T depressions with or without T wave inversions in a patient with cardiac pain or with a disease known to impair the coronary blood supply The non specificity of such RS T and T wave changes is well known [64] Therefore coronary insufficiency is not a justifiable electrocardiographic diagnosis and is made by the electrocardiographer only with knowledge of the clinical history Even then the electrocardiographic changes should be interpreted in terms of myocardial, not coronary, disturbance The RS T depressions and T wave inversions in cases under discussion do not disclose the exact myocardial pathology, i e, whether necrosis is present or only ischemia but indicate only the localization of the myocardial disturbance, i e, in the sub-

endocardium The electrocardiographic changes may then be said to be due to subendocardial ischemia or necrosis Although subendocardial ischemia or necrosis often occurs without a recent coronary occlusion an acute coronary occlusion may produce subendocardial ischemia or necrosis rather than transmural infarction and may thus appear clinically and electrocardiographically as acute coronary insufficiency '

Even coronary occlusion with through and through (transmural) infarction may at the outset be characterized by electrocardiographic RS T depressions and T wave inversions In the presence of previous myocardial infarction or of left ventricular hypertrophy transmural infarction may be represented on the electrocardiogram by no more than ST depressions and/or T wave inversions Conversely and finally in coronary insufficiency without coronary occlusion there have been instances of through and through infarction with RS T elevations and Q waves in the electrocardiogram [19]

Conclusion

Acute coronary insufficiency is not a distinct clinical entity and adds confusion to cardiac terminology Terminology would be clarified if care were taken to distinguish a physiologic disturbance a pathologic lesion and a clinical picture Coronary insufficiency has long denoted a physiologic disturbance It may result from recent or old coronary occlusion extreme coronary narrowing non coronary cardiac diseases or from any factor which diminishes coronary blood flow reduces its oxygen content or increases myocardial work disproportionate to coronary blood flow This is too broad a category to define a specific myocardial lesion or a specific clinical entity

Coronary thrombosis or occlusion refers to a pathologic lesion It is sometimes employed to denote a clinical picture namely the symptoms and signs of the resulting myocardial infarction It would be preferable not to use the term coronary occlusion in a clinical sense because it may or may not be followed by myocardial infarction and the clinical picture varies significantly according to the variable myocardial disturbances Myocardial infarction is a term used to describe a pathologic change but also a clinical (including electrocardiographic) picture because the clinical and electrocardiograph features are actually determined by the infarct varying only with the extent and location of the myocardial injury

Angina pectoris is a clinical syndrome Its underlying pathology is variable but most commonly comprises coronary occlusion severe coronary narrowing calcific aortic stenosis or syphilitic ostial stenosis It may be induced by any disease or disturbance causing coronary insufficiency Coronary insufficiency is the physiologic disturbance underlying angina pectoris as it is the physiologic disturbance underlying myocardial necrosis or infarction The coronary insufficiency underlying angina pectoris is transient relatively less intense and essentially irreversible as compared with the usually permanent and severe myocardial destruction accompanying myocardial infarction

The diagnosis *angina pectoris* (or persistent angina pectoris) should be employed even when a patient experiences cardiac pain which is more prolonged than the ordinary attack of angina pectoris provided fever leukocytosis and shock do not develop and the characteristic signs of myocardial infarction are absent But one should make a careful search for the possible factor which accounts for the longer duration of the pain Often this may be a coronary occlusion which has induced myocardial ischemia but not infarction because collateral circulation maintains the viability of the affected muscle

When RS T depressions with or without T wave inversions occur in a patient with cardiac pain or a condition known to produce coronary insufficiency a diagnosis of (subendocardial) myocardial ischemia or necrosis should be made If fever leukocytosis shock etc develop the diagnosis is subendocardial infarction not merely ischemia In the presence of marked left ventricular hypertrophy or previous myocardial infarction ST depressions and T wave inversions may occur even with transmural infarction

There is no need for the term acute coronary insufficiency to denote a clinical entity and such usage should be abandoned Coronary insufficiency should be employed only to designate the physiologic disturbance caused by an inadequate or unoxygenated coronary blood flow In clinical diagnosis designation of the physiologic disturbance is

inadequate, it is essential to indicate as clearly as possible the underlying myocardial pathology and the etiologic factors

Chapter 18

ANGINA PECTORIS

Diagnosis, Differential Diagnosis, Prognosis and Treatment

DIAGNOSIS

The identification of a pain or distress in the chest as angina pectoris does not constitute a complete diagnosis for angina pectoris is a symptom complex and not a disease However the recognition of angina pectoris is an important diagnostic step since its presence denotes some serious underlying cardiac ailment usually severe coronary atherosclerosis with or without occlusion

THE CLINICAL HISTORY

The diagnosis of angina pectoris depends primarily on the clinical history and not on objective findings However the presence of an underlying cardiac disease or a positive response to tests disclosing coronary insufficiency supports the diagnosis of angina pectoris

The essential diagnostic features of angina pectoris are (1) the paroxysmal occurrence of the pain (2) its brief duration (3) its characteristic location radiation and quality (4) its precipitation by effort and relief by rest and (5) its relief by nitrites

These points require brief annotation (1) Sometimes there is a dull persistent pain or ache between the paroxysms varying in intensity but there must also be definite paroxysms to warrant the diagnosis of angina pectoris

(2) Attacks of angina pectoris usually last less than five minutes and rarely exceed fifteen minutes Apparent paroxysms of angina pectoris of longer duration probably denote an acute coronary occlusion without infarction or impending myocardial infarction even when there are no significant electrocardiographic abnormalities At other times prolonged attacks of angina pectoris denote that the predisposing or precipitating factor is persisting longer than usual Finally, as a rule severe or prolonged cardiac pain indicates an acute coronary occlusion with myocardial infarction, which will be disclosed by characteristic clinical and electrocardiographic findings (Chapter 20)

(3) The location of the pain over the sternum or precordium is characteristic but not specific for angina pectoris Radiation to the left shoulder arm and wrist or both arms is usually confirmatory of angina pectoris but not essential for the diagnosis The strangling constricting or compressing quality of the pain and the frequent association of angor animi are valuable diagnostic features Dull or sticking pains and pain in the region of the cardiac apex in the lower part of the left axilla or below the left breast are rarely manifestations of angina pectoris

(4) The diagnosis of angina pectoris is equivocal if there is no history of the precipitation of the pain by effort and its relief by rest But sometimes no such history is elicited because the patient has avoided all but the mildest activity or because he has not walked far enough or rapidly enough to induce pain He should be asked specifically Do you have pain on walking rapidly on hurrying or on walking uphill? Can you continue the same pace once the pain begins? Is it relieved by slowing your pace or by stopping? When the pain is induced by walking it has an arresting quality which compels the patient to stop or sharply reduce his speed The pain of angina pectoris occurs frequently with vigorous or prolonged conversation especially on the telephone and with excitement anger or other emotional states This relationship should not be interpreted as indicating that the pain is psychogenic especially if there are other occasions when the pain is produced in typical fashion by effort and relieved promptly

by rest. Pain induced *only* by emotional states is often due to angina pectoris if its quality, location and radiation are characteristic, but it should be brief and paroxysmal and relieved promptly by nitroglycerin. It may be necessary to test the effect of effort and rest in order to be certain of their relationship to the pain. Sternal or precordial pain which is induced by fatigue or after working long but which is not promptly relieved by rest should not be interpreted as a manifestation of angina pectoris. Similarly, anterior chest pain which occurs only or especially when the *patient sits down and relaxes after a hard day* is not angina pectoris. Reproduction of the pain by rapid walking under appropriate circumstances and its prompt relief by rest help to confirm the diagnosis of angina pectoris. On the other hand, reproduction of the pain by direct pressure over the costochondral *junctions, by special motions of the chest wall, neck or left arm, or by hyperventilation* serves both to exclude the diagnosis of angina pectoris and to reassure the patient.[85]

(5) The response to nitrites, especially nitroglycerin or amyl nitrite, is often helpful in diagnosis. The diagnosis of angina pectoris is *supported if the relief of the pain, pressure* or indigestion, is definite, prompt and unquestioned by the patient. I have, however, observed patients suffering from pain in the chest which was relieved by nitroglycerin but which was later proved to be unrelated to cardiac or coronary disease. However, this is extremely *uncommon and care should be* taken to evaluate the effectiveness of the nitroglycerin by repeated trials and by timing its onset of action and relief. If the pain occurs regularly under given circumstances, prevention of the pain by prophylactic administration of nitroglycerin just be*fore the pain is apt to occur is confirmatory* of angina pectoris.

OBJECTIVE EVIDENCES OF CARDIAC DISEASE

When the essential symptomatic criteria are satisfied, the diagnosis of angina pectoris *may be made with certainty even in the* absence of objective findings. In doubtful cases of pain in the chest, however, a suspected diagnosis of angina pectoris may be supported by finding hypertension, significant cardiac enlargement, aortic valvular disease or such electrocardiographic abnormalities as frequently accompany severe coronary artery disease (see p. 433). Occasionally it is possible to take an electrocardiogram during an attack of pain; the presence of a transient ST de*pression and lowering or inversion of the T waves with a return to normal soon after the* pain subsides strongly suggest that the pain is a manifestation of angina pectoris. Occasionally RS-T elevations have been observed during an attack of angina pectoris resembling those commonly seen with acute myocardial infarction[1,8,82,89] (p. 522). However, it should be stressed that angina *pectoris due to advanced coronary* atherosclerosis may be present without abnormal physical signs in the heart and without roentgen ray or electrocardiographic evidence of myocardial disease in more than one quart[er] of patients. When patients are observed early in the course of their angina pectoris *and there is no history of previous myocardial infarction*, there may be no objective abnormalities in at least 75 per cent of cas[es].

TESTS OF CORONARY RESERVE AND CORONARY INSUFFICIENCY

It has been mentioned that ther[e] ... margin of safety whereby a diminutio[n] ... *coronary blood flow or an increa[se]* ... myocardial blood requiremen[ts] ... without resulting in coronary ... angina pectoris. This margin ... coronary reserve. In subjects ... impaired coronary circulatio[n] ... reserve is already so dimin[ished] ... *factor tending to cause anox[ia]* ... result in myocardial anoxia ... duce angina pectoris or che[st] ... changes. This principle has ... the basis of tests for corona[ry] ... The demonstration of a di[minished] ... reserve by such tests, ... *pain suggesting angina* ... as supporting the con... actually represents an ... the factors utilized t... sufficiency in patient[s] ... onary reserve are ge[n] ... exercise. These tests ... *very small percenta[ge]* ... pectoris an accura[te] ... always possible on ... history and routi[ne] ... mented if necess[ary] ... between which th[e] ...

the circumstance under which the pain occurs, its character location, radiation and duration and the effect of rest and nitroglycerin The statement that the history is *often* atypical and not diagnostic is certainly not valid in my clinical experience However, objective tests are useful in problems of insurance and medicolegal practice because of the possibility that a history of angina pectoris may be fabricated

Anoxemia Test (Hypoxemia Test)[67, 46, 110, 108]

Generalized anoxemia is induced by having the subject breathe a mixture of 10 per cent oxygen and 90 per cent nitrogen for 20 minutes unless cardiac pain is experienced before electrocardiographic abnormalities are noted, according to the criteria of Levy[61] (1) The sum of the RS 1 deviations in leads I II, III and V_4 exceeds by 3 mm or more that of the control According to several observers, there is usually not more than 0 5 mm and never more than 1 mm displacement of the RS T segment in any standard lead in normal individuals (2) There is partial or complete reversal of the direction of the T wave in lead I accompanied by an RS T deviation of 1 mm or more in this lead (3) There is a complete reversal of the T wave in lead V_4 regardless of any associated RS-T deviation in this lead Burchell and his as

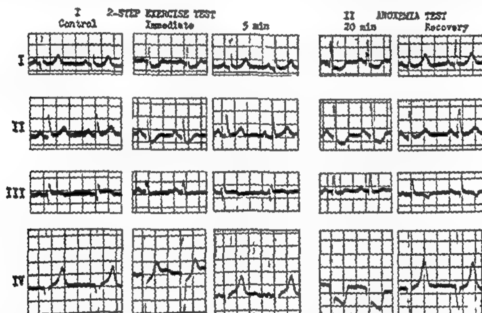

Fig 98 Exercise and anoxemia test in coronary artery disease on same patient Positive test for coronary insufficiency with both tests Pronounced S T segment depressions

that interval ■ Turner and Morton[110] suggest *that 10 minutes suffice The subject is per*mitted to breathe 100 per cent oxygen for one minute immediately after concluding the test or if there are any unpleasant reactions Electrocardiograms are taken just before the test and at five-minute intervals until the electrocardiogram has returned to its control form It has been recommended that the "arterial" oxygen saturation during the test be controlled with the aid of an ear oximeter and that the oxygen saturation should be maintained at 75 per cent[110] or 70 per cent[107, 76] The test ■ termed positive (Fig 98) and considered indicative of coronary insufficiency or diminished coronary reserve if pain occurs during the procedure or if the following sociates[17] found that the precordial leads were more informative than the standard leads and could be used exclusively if desired According to Turner and Morton[110] an S T depression of 2 mm or more in lead V_4 indicates a positive test, but other leads should also be recorded Characteristic chest pain during the test is probably due to coronary insufficiency and as a rule is accompanied by the diagnostic electrocardiographic changes, but frequently these electrocardiographic abnormalities appear without pain The S T depressions appear to denote that myocardial anoxia is most pronounced in the subendocardial layer and that this is electrically positive relative to the subepicardial layer A negative test does not exclude angina pectoris

or coronary insufficiency. As a matter of precaution, it is both unwise and unnecessary to perform an anoxemia test in a patient whose 12 lead electrocardiogram discloses abnormalities indicative of myocardial damage.

Patterson, Clark and Levy[75] found the test to be electrocardiographically positive in 49 per cent of 157 cases of coronary sclerosis. In an additional 20 per cent the occurrence of pain without electrocardiographic changes also offered presumptive evidence of coronary insufficiency. Compared to this total of 69 per cent positives in patients with coronary disease, there was no instance of pain or a positive electrocardiographic test in 136 normal subjects. Other observers have obtained positive tests in 30 to 50 per cent of cases with probable or definite clinical coronary disease, in 15 to 20 per cent of suspected cases and in 0 to 2.7 per cent of normals or slightly suspected cases.[9] Bjorck[10] observed a positive anoxemia test in 9 patients with cardiac neurosis without organic heart disease. There was a negative response when 0.5 mg. ergotamine tartrate was given intramuscularly or subcutaneously 20 minutes before the anoxemia. Dihydroergocornine (0.5 mg.) has been similarly used.[75]

Although occasional unpleasant and even serious reactions have been observed during the hypoxemia test[116] (dizziness, headache, drowsiness, nausea, cyanosis, anxiety, numbness, tingling, restlessness, hysteria, vasovagal syncope, air hunger, chest pain, arrhythmia, convulsions and pulmonary edema), the serious ones have become rare as technique has improved and been standardized and discretion used in the choice of subjects. *Burchell and his associates*[17] *performed* 730 hypoxemia tests without a fatality. Among the contraindications to the anoxemia test are obvious cardiac enlargement, definite previous myocardial infarction, chronic pulmonary disease, severe anemia, cyanosis, pregnancy, acute illness, advanced debility. Because of the risk of reactions, however small, the need for technical equipment and special skill in the choice of patient and in the interpretation of findings, the anoxemia test is not yet suitable for general use.

Exercise Test of Coronary Reserve[86, 111, 85]

Exercise strains the coronary reserve by increasing the myocardial need for blood. A standardized amount of exercise is performed (e.g., the two-step test of Master and Oppenheimer[67] or that of other authors[87, 103a]). In patients with a diminished coronary reserve the exercise may produce pain or distinctive electrocardiographic changes.[111, 86] The test is not performed until a resting electrocardiogram has been taken and found to be normal. A positive test is associated with the following changes according to Sokolow and Twiss[111]:

(a) RS-T segment depression or elevation of 1 mm. or more in lead I, of 1.5 mm. or more in lead II, of 1.5 mm. or more in lead III and 2 mm. or more in lead IV. The base line at the beginning of the QRS, i.e., the P-Q segment, is used as the reference level determining S-T deviations. (Note also that Scherf and Schaffer[9] regard an S-T depression of less than 2 mm. as *not* definitely abnormal.)

(b) The conversion of an upright to a diphasic or inverted T wave in lead I, II or IV.

(c) The development of bundle branch block. Right bundle branch block has been observed during spontaneous attacks of angina pectoris and after exercise in patients with clinical coronary disease.[9]

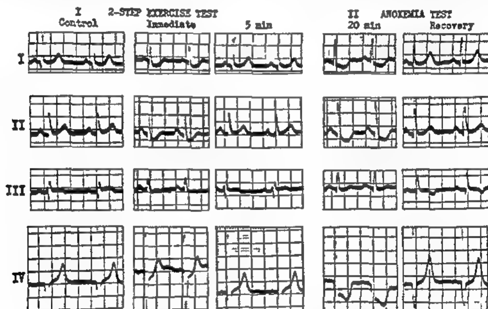
Twiss and Sokolow[111] reported that cardiac pain developed during the test in 45 of 66 patients known to have angina pectoris. The above mentioned significant electrocardiographic abnormalities appeared in two thirds of those who experienced pain during the test and in 56 per cent of the total number of patients with angina pectoris regardless of the development or absence of pain.

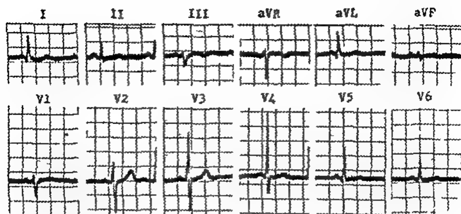
The two-step exercise electrocardiogram test *as described by Master*[86] *involve the* performance within 1½ minutes of usually 15 to 25 trips up and down two steps each 9 inches high. He stresses the importance of standardizing the amount of exercise, the number of trips being varied with the age, weight and sex of the patient according to published tables. The exercise is stopped promptly if the patient experiences pain. The test is performed only if the resting 12 lead electrocardiogram is normal and there is no history suggesting recent or impending myocardial infarction. If the so called single two step electrocardiogram as just described is negative, a double two-step test is administered; this involves twice as many trips as in the single test but in three minutes instead

the circumstance under which the pain occurs, its character, location, radiation and duration and the effect of rest and nitroglycerin. The statement that the history is *often* atypical and not diagnostic is certainly not valid in my clinical experience. However objective tests are useful in problems of insurance and medicolegal practice because of the possibility that a history of angina pectoris may be fabricated.

Anoxemia Test (Hypoxemia Test)[81, [illegible], 110, 108]

Generalized anoxemia is induced by having the subject breathe a mixture of 10 per cent oxygen and 90 per cent nitrogen for 20 minutes unless cardiac pain is experienced before electrocardiographic abnormalities are noted, according to the criteria of *Levy*[81] (1) The sum of the RS-T deviations in leads I, II, III and V_4 exceeds by [illegible] mm or more that of the control [illegible] According to several observers, there is usually not more than 0.5 mm and never more than 1 mm displacement of the RS-T segment in any standard lead in normal individuals. (2) There is partial or complete reversal of the direction of the T wave in lead I, accompanied by an RS-T deviation of 1 mm or more in this lead. (3) There is a complete reversal of the T wave in lead V_4 regardless of any associated RS-T deviation in this lead. Burchell and his as-





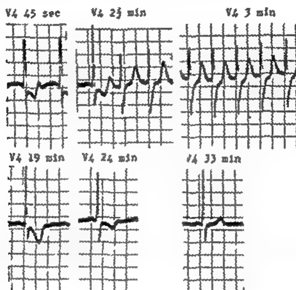


Fig 98 Exercise and anoxemia test in coronary artery disease on same patient. Positive test for coronary insufficiency with both tests. Pronounced S-T segment depressions.

that interval.[81] Turner and Morton[110] suggest that 10 minutes suffice. The subject is permitted to breathe 100 per cent oxygen for one *minute immediately after concluding the test* or if there are any unpleasant reactions. Electrocardiograms are taken just before the test and at five-minute intervals until the electrocardiogram has returned to its control form. It has been recommended that the "arterial" oxygen saturation during the test be controlled with the aid of an ear oximeter and that the oxygen saturation should be maintained at 75 per cent[110] or 70 per cent.[107, 76] The test is termed positive (Fig 98) and considered indicative of coronary insufficiency or diminished coronary reserve if pain occurs during the procedure or if the following sociates[17] found that the precordial leads were more informative than the standard leads and could be used exclusively if desired. *According to Turner and Morton*[110] an S-T depression of 2 mm or more in lead V_4 indicates a positive test but other leads should also be recorded. Characteristic chest pain during the test is probably due to coronary insufficiency and, as a rule, is accompanied by the diagnostic electrocardiographic changes but frequently these electrocardiographic abnormalities appear without pain. The S-T depressions appear to denote that myocardial anoxia is most pronounced in the subendocardial layer and that this is electrically positive relative to the subepicardial layer. A negative test does not exclude angina pectoris

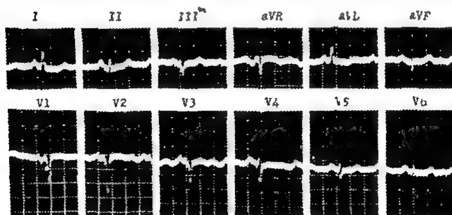

Fig. 99 Acute myocardial infarction following two-step exercise electrocardiogram

injury to the pectoralis minor tendon (5) Peptic gastric or duodenal ulcer (6) Cholelithiasis and chronic cholecystitis (7) Esophagospasm (8) Diaphragmatic or paraesophageal hernia (9) *Bronchial asthma* (10) Radiculitis secondary to cervical dorsal spondylitis or displaced cervical disk (11) Subacromial bursitis or periarthritis of the left shoulder (12) Cervical rib (13) Scalenus anterior syndrome (14) Metastatic cervical lymph nodes compressing the brachial plexus (15) Pleurisy (16) Pericarditis (17) Aneurysm of the aorta (18) Carcinoma or suppuration of the lung or *mediastinal neoplasm* (19) Diaphragmatic flutter[13] (20) Carotid sinus syndrome[23]

The differentiation of angina pectoris from acute myocardial infarction will receive special discussion (see p 554)

Relation of the Pain to Exertion

Pain in the above conditions is chiefly distinguished from angina pectoris by being unrelated to general bodily exertion especially walking rapidly or uphill The pain secondary *to subacromial bursitis arthritis of the* shoulder and spine or local disease of the chest wall may be precipitated by exercise of the local areas but not by general bodily effort Active or passive movement of the left arm or cervical and thoracic spine through its complete range of motion or deep inspiration coughing or sneezing may reproduce the pain and disclose its noncardiac origin, immobilization of the affected part may eliminate or diminish the pain even during general bodily exertion Reeves *and* Harrison[63] have stressed the diagnostic and therapeutic value of the *reproduction of the patient s chest pain* The occurrence of the pain with emotional states is not decisive being as common with neuroses and functional disturbances of the gastrointestinal tract as with angina pectoris, but the character location and radiation of the pain are often different

Character and Location of the Pain

The character and location of nonanginal chest pain often aid in differentiation from angina pectoris A dull ache in the precordial *region or* above and to the left of the heart is common in neurotic persons or as a result of *pectoral myalgia or neuralgia A dull ache* or sharp, sticking or stabbing pain in the region of the cardiac apex or *in the left breast* also occurs frequently in neurotic subjects In addition, there is often a complaint of excessive fatigability, palpitation, diffuse pains in different parts of the body and difficulty in taking a deep breath (characterized objectively by sighing respiration) The pain often *radiates around the ribs and to the left subscapular region* In addition to the difference in site and character of this pain it is usually indefinite in onset as compared with the paroxysmal nature of the attacks in angina pectoris The pain occurs at rest as well as with effort and especially when the patient is fatigued There is often an hyperesthesia in the painful area, usually in the segmental *distribution of D4 and D5 rather than of* C8 and D1 as in angina pectoris A similar type *of pain occurs in subjects with indigestion* especially in middle-aged obese men and women This form of pain, often in association with other diffuse pains variously located in the chest and abdomen, results from gastrointestinal gaseous distention

Dull and sticking precordial pain or discomfort usually associated with palpitation frequently results from paroxysmal *tachycardias* and *runs of premature beats* However with very rapid ventricular rates, ectopic tachycardias may induce myocardial ischemia and true anginal pain A careful history and examination readily disclose the relation of the pain to the arrhythmia

The pain of gastric and duodenal ulcer is usually situated in the epigastrium and lower sternal region, it has a burning or boring quality is unrelated to effort and occurs usually one to four hours postprandially whereas *angina pectoris is apt to* occur more promptly after meals and usually *only with postprandial exertion Ulcer* pain ordinarily is relieved rapidly by alkalis and milk

The patient with bronchial asthma may describe substernal pain or pressure on rapid walking which may be interpreted as angina pectoris A careful history and examination and the effectiveness of sublingual Isuprel and the ineffectiveness of sublingual nitroglycerin usually differentiate the two conditions

The pain due to pleurisy or pericarditis is unlikely to be confused with angina pectoris because of associated clinical symptoms, the *presence of fever and other objective evidences* of infection and local disease the sharp nature *of the pain and its frequent occurrence* with deep inspiration

Expanding or dissecting aneurysms pro-

duce a more constant crushing type of pain than is associated with angina pectoris

Occasionally I have seen cases of carcinoma or suppuration of the left upper lobe of the lung with chest pain interpreted as angina pectoris The pain is usually more intense and persistent than that of angina pectoris although it may be located in the precordium and may radiate to the left upper extremity

Differentiation of Local Lesions of the Chest Wall by Physical Examination

Physical examination often reveals the local origin of pectoral pain Careful palpation of the ribs may disclose a fracture due perhaps to a metastatic lesion or involvement by a myeloma Examination of the costochondral junctions especially on the left side may demonstrate that the pain is due to an arthritis or to a traumatic non-suppurative painful swelling of one or more of these joints (Tietze's syndrome[6, 7, 10]) or to a fibrositis This occurs more commonly than is generally recognized Local infiltration of 1 per cent procaine often relieves the pain but similar relief has been reported in cases of angina pectoris Occasionally digital manipulation may demonstrate that the slipping of one rib under another is the cause of precordial pain The pain is usually prevented by strapping the affected chest wall A slipping rib cartilage[67] may also cause chest pain which has been confused with angina pectoris Usually the cartilages of the eighth ninth or tenth rib are involved having been dislocated or displaced by fracture The pain can be reproduced by digital examination with the patient supine his knees flexed Manipulation of the movable rib cartilage causes pain and an audible click The pain may be cured by strapping or resection of the affected cartilage Strain of the left pectoralis minor muscle was described as a common cause of chest pain in soldiers[69] Skeletal pain may be distinguished by the relief obtained following procaine infiltration of local tender areas or between the spinous processes of the lower cervical and upper thoracic vertebrae[84]

Roentgenologic Differentiation of Biliary Gastrointestinal Aortic Pulmonary and Skeletal Disease

The underlying cause of many types of chest pain is often determined or proved by roentgenologic examination This applies to cholelithiasis peptic ulcer diaphragmatic or esophageal hernia aortic aneurysm pleuropulmonary disease subacromial bursitis arthritis of the left shoulder or cervicodorsal spine or destructive lesions of the ribs Roentgenologic examination of the chest including its bony cage of the cervical spine and left shoulder joint and of the esophagus stomach duodenum and biliary tract are often essential to the accurate interpretation of pain simulating angina pectoris but the similarity in pain is usually very superficial It is also important to remember that the patient with duodenal ulcer hiatus hernia and other conditions may also be suffering from angina pectoris A careful history and therapeutic tests differentiate the two types of pain

Differentiation of Angina Pectoris from Pain Due to Skeletal Lesions

Various forms of cervicodorsal neuritis may produce pain which is mistaken for angina pectoris This pain is rarely retrosternal is usually sharp or aching in quality and has no paroxysmal relation to general bodily exertion One fairly common and often unrecognized cause of pain referred to the precordium and left arm is a traumatic or postural strain of the muscles and ligaments about the lower cervical and upper dorsal spine An underlying spondylitis displaced cervical disk or other lesions of the vertebrae or articulating surfaces may also be present[71] There is often a history of stiff neck The disturbance may also cause occipital headache or pain of the upper back But the chief pain is usually in the left shoulder arm forearm fingers and upper precordium[84] Relief of the pain may be obtained by the application of a cervical collar supporting the skull or by suspension in traction Semmes and Murphy[92] described a syndrome simulating angina pectoris and characterized by pain in the neck left shoulder and arm and precordium and by sensory changes in the index and middle fingers due to unilateral rupture of the sixth cervical intervertebral disk The pain was due to compression of the seventh cervical nerve root on the left side Cure or relief was effected by subtotal hemilaminectomy under local anesthesia

Sometimes advanced osteoarthritis or destructive lesions of the upper dorsal spine or lesions of the spinal cord or nerve roots produce radicular pains of the precordium[4, 2] These pains occur in band like zones which are usually complete and involve the anterior

and posterior chest wall corresponding to the involved nerve segments Often there is a similar band like area of objective hyperalgesia (Head zone) which has a complete or incomplete segmental distribution Angina pectoris is more likely to produce pain radiations which skip from one root zone to another and its segmental distribution is usually incomplete The pain due to spinal lesions is not related to general bodily effort but is induced by motions of the spinal column or by factors increasing intraspinal pressure such as coughing and sneezing

Periarthritis of the shoulder joint subacromial bursitis and calcification of the shoulder tendons are common lesions often associated with pain not only about the shoulder but also in the arm and anterior chest wall When the left shoulder is involved the pain may be interpreted as angina pectoris Ordinarily the precipitation or exaggeration of the pain by elevation or rotation of the arm the limitation of motion about the shoulder and the absence of relationship to walking distinguish the pain due to these lesions from that of angina pectoris

However the differential diagnosis is often complicated because of the frequent association of disease of the shoulder region and angina pectoris Furthermore the shoulder disturbances are not infrequently the consequence or sequel of a previous acute coronary occlusion (see p 545) Therefore the orthopedic or roentgenologic demonstration of bursitis calcification or periarthritis of the shoulder should not be interpreted as a complete explanation for the patient's pain without a careful clinical history and examination, and a roentgenologic and electrocardiographic study of the heart to determine or exclude the presence of associated angina pectoris and coronary or other cardiac disease

Occasionally pain in the left upper extremity and precordium is due to compression of fibers of the brachial plexus by a *cervical rib* or against the first thoracic rib (*scalenus anterior syndrome*) In the latter syndrome a high fixation of the ribs and sternum or a low position of the shoulder and brachial plexus leads to irritation and stimulation of the plexus with secondary spasm and shortening of the scalenus anterior [7] This causes further elevation of the first rib and compression of the brachial plexus The pain in the precordium and arm is sharp or aching and often radiates to the fourth and fifth fingers It may be associated with numbness, tingling or other paresthesias Relief of the pain by the injection of procaine into the scalenus anterior muscle is helpful in the diagnosis The presence of cervical rib is demonstrated roentgenographically Cure is effected by surgical removal of the cervical rib or by resection of a portion of the scalenus anterior muscle depending on which is the cause of the pain

The *hyperabduction syndrome*, due to constriction of the subclavian artery and brachial plexus is caused by hyperabduction of the arms during sleep or from trauma or postural strain It is characterized by pain in the upper extremity paresthesias and numbness in the hand and fingers

Brachialgia statica paresthetica, occurring only at night and after the patient has gone to sleep is also characterized by pain in the arm and transient paresthesia and is attributed to relaxation of the shoulder girdle during sleep and consequent compression of the subclavian artery and brachial plexus between the clavicle and first rib

PROGNOSIS

The prognosis of angina pectoris is essentially that of the causative underlying disease This is discussed in the individual chapters on coronary artery disease aortic stenosis, syphilitic heart disease etc In general angina pectoris associated with syphilitic heart disease or aortic stenosis has a more serious prognosis than when associated with severe coronary disease Syphilitic aortitis with angina pectoris occurring at night and in the recumbent position has a particularly unfavorable outlook Angina pectoris in cases of *calcific aortic stenosis* is usually a *late symptom*, and the duration of life after its onset is brief The development of angina pectoris in young subjects with rheumatic aortic valvular disease is particularly ominous although occasionally the anginal paroxysms subside In the largest group of cases of angina pectoris, those due to coronary atherosclerosis, the prognosis is more encouraging than in the groups due to the other major causative diseases When there is a definitely remediable contributory factor such as anemia or hyperthyroidism the outlook may be more favorable than in the absence of such factors

Sometimes the cure of a contributing causative factor may lead to the complete disappearance of the paroxysms of angina pectoris

The danger of sudden death is an intrinsic element of the syndrome of angina pectoris and compels a note of caution and reserve in any attempt at predicting the outcome Sudden death occurs in about 10 to 15 per cent of cases in a much larger percentage of cases death is not sudden but unexpected and rapid after a brief manifest attack of myocardial infarction Sudden death is believed to result usually from ventricular fibrillation or cardiac standstill to which the anoxic myocardium or heart with diminished coronary reserve is particularly susceptible However it is not understood why the occurrence of sudden death is not clearly correlated with the frequency or severity of the anginal attacks and it is impossible to prognosticate from either the clinical history or findings which patient with angina pectoris will die suddenly

The advent of angina pectoris does not forebode imminent demise Most patients live for five to ten years after the onset of this symptom Earlier estimates of duration of life averaging four to five years have been revised progressively upward by later studies Of about 500 patients followed by White et al [118] 90 per cent succumbed after an average period of eight years following the onset of symptoms Those still alive had survived for an average interval of 18 4 years A follow up of 1700 cases[109] disclosed an average survival period of 4 6 years for the 679 patients who had died but 32 8 per cent of the males and 34 5 per cent of females were still living after five years and 10 per cent of each sex survived for at least ten years In another follow up study of 6882 cases of angina pectoris for 5 to 23 years[11] about 15 per cent succumbed in the first year after onset thereafter there was an average annual mortality of 9 per cent There was a 5-year survival period of 58 4 per cent compared with a rate of 86 9 per cent for the normal population and a 10 year survival of 37 1 per cent compared to an expected 70 4 per cent Like others[70] I have seen many patients who have survived for more than ten years and occasionally for more than fifteen or twenty years

The hereditary factor sometimes appears important in prognosis A history of angina pectoris and coronary thrombosis in many members of the family especially in the parents with death at an early age bespeaks *an unfavorable and brief course The age of* onset is significant in that the earlier the onset the lower the age at death even when the duration of angina pectoris is relatively long Furthermore when angina pectoris begins in the thirties or forties, it often denotes an hereditary vascular weakness and a likelihood *of early complications and death Pronounced* hypertension or cardiac enlargement previous myocardial infarction and heart failure are among the associated findings which tend to diminish the duration of survival but there are numerous exceptions The association of angina pectoris with diabetes is a very *unfavorable combination*

The progress of cases of angina pectoris may follow any one of many courses Sometimes with or without a significant change in the severity or frequency of the attacks the patient dies suddenly months or years after the initial paroxysm More commonly the course of the disease is punctuated by one or more clinically diagnosed attacks of acute myocardial infarction before death supervenes This occurs in at least 25 per cent of the cases of angina pectoris In some instances there is no positive evidence of an acute myocardial infarction but a sudden sharp increase in the frequency and severity of the anginal paroxysms suggests strongly that a large coronary vessel has become occluded In a large number of cases the clinical course is characterized by the gradual or sometimes sudden development of congestive heart failure usually late in the course of the disease As a rule it may be assumed although this is not always clinically apparent that the failure appeared after the closure of additional coronary vessels and a consequent extension of myocardial damage In still other cases an associated hypertension and diffuse atherosclerosis determines the ultimate outcome the patient eventually succumbs to cerebral thrombosis or embolism cardiac failure or renal insufficiency Finally some patients never develop any serious complications referable to their underlying cardiac disease but die of intercurrent infections carcinoma or other independent disease

Angina pectoris may disappear for long periods of time or permanently even after it has been present for months or years Often this denotes that the living area of myo

cardium which had previously suffered recurrent anoxia and thereupon had engendered pain has finally been destroyed and undergone fibrosis as a result of a complete coronary occlusion Following a clinical attack of acute myocardial infarction the patient may be able to resume moderate activity without recurrence of pain even with exertions that formerly produced it The converse has also been noted i e the onset of angina pectoris following a clinical episode of myocardial infarction Angina pectoris frequently subsides or disappears completely with the development of congestive heart failure or permanent atrial fibrillation This may be explained by the reduction in activity which these complications impose or by the fact that they usually appear after an acute coronary occlusion with death of the pain producing myocardial tissue The disappearance of angina pectoris after correction of anemia has been mentioned

The patient with angina pectoris may be hardly inconvenienced or his activity may be involuntarily so restricted that he is a chronic cardiac invalid Most patients, for at least a few years after the initial episode remain outwardly fairly normal individuals, capable of conducting their business or profession on a somewhat diminished scale of activity, or of earning their livelihood at their usual occupation

TREATMENT

The treatment of angina pectoris is designed primarily to prevent or reduce the frequency of attacks, the paroxysm itself *usually requires no special treatment as it is* brief in duration and subsides spontaneously Occasionally however, specific therapy is indicated to prevent an attack or to relieve pain which occurs frequently even with the patient at rest The prevention of attacks of angina pectoris depends on the treatment of the underlying or contributing causative diseases and the elimination or cure, when possible of the factors which initiate or contribute to the precipitation of the paroxysms

Management of the Underlying Disease

The primary approach in the treatment of any given case should be the determination and proper management of the underlying cause This is discussed under the respective headings, e g , coronary artery disease syphilitic heart disease, aortic valvular disease Measures to improve the basic deficiency in blood supply to the heart are discussed later in this chapter

Treatment and Elimination of Contributing Factors

The administration of liver extract in pernicious or other primary anemias of iron in the iron deficiency anemias or transfusions in anemia due to acute hemorrhage may prevent entirely the occurrence of angina pectoris, even though the basic underlying coronary disease or valvular disease is unaffected In addition it may be necessary to treat the original cause of a secondary anemia when this can be discovered e g , bleeding hemorrhoids peptic ulcer, fibroid uterus or improper diet Similarly, in cases of angina pectoris with hyperthyroidism the latter should be corrected (p 1011)

Although the relation of *disturbances of the gastrointestinal and biliary tract* to angina pectoris is still uncertain their correction may be followed by an amelioration or disappearance of cardiac pain A rigid treatment of peptic ulcer or of functional pylorospasm and gastric hyperchlorhydria by bland frequent feedings alkalis and sedatives, not only relieves the ulcer symptoms but may reduce the frequency of angina pectoris When symptoms are caused by a diaphragmatic hernia they may be controlled by small meal antispasmodics, and the maintenance of the erect position for one half hour or longer postprandially Rarely operative correction is necessary and may also alleviate anginal pain

Cholelithiasis and chronic cholecystitis are *often asymptomatic, especially if the intake is* moderate in amount and bland in quality However, often the severity and persistence of symptoms warrant surgical removal of the gallbladder Cholecystectomy in such cases has been reported as alleviating not only the symptoms referable to the gallbladder but also the anginal symptoms This surgical procedure has been followed in some cases by the disappearance of electrocardiographic abnormalities

The eradication of *foci of infection* such as a diseased tooth or the alleviation of other painful somatic foci to which anginal pain is referred or which help to bring latent painful cardiac impulses to the clinical level, may be followed by a disappearance or diminution of attacks of angina pectoris

Although there is no convincing proof that *tobacco* directly causes angina pectoris except possibly in some sensitive individuals, it is my custom to urge that patients stop smoking when they first consult me for angina pectoris. Statistical studies seem to suggest a significant relationship between smoking and angina pectoris.[81, 43] The mechanism by which tobacco may damage the coronary vessels or heart is not clear. Ordinary and denicotinized cigarettes may have similar effects.[illegible, 9] Often patients feel better generally after foregoing tobacco, even when there is no striking causal relationship between smoking and cardiac pain.

Avoidance of Precipitating Factors

Patients with angina pectoris rapidly learn by themselves to avoid those forms of bodily exertion which are the commonest immediate causes of pain. Usually it is necessary to reduce the distance and especially the speed of walking. To avoid being conspicuous, many patients stop repeatedly in front of stores and pretend they are window shopping. Often the patient may avoid pain by changing his manner of transportation so as to reduce the walking distance to his train or subway. He may have to change his route if it involves walking uphill. Running for buses or trains must be prohibited. The patient must learn to allow sufficient time so that hurrying is unnecessary. Occasionally patients find that if they walk a block until mild pain develops and rest long enough for it to subside, they may then walk moderate distances without discomfort. Walking after meals should be shunned; if essential, the meal should include minimal quantities and the patient should take nitroglycerin prophylactically before walking. I have seen patients whose pain after walking occurred only on their way to the train in the morning. However, by postponing breakfast until they arrived at a restaurant within a block or so of their office, a paroxysm of angina pectoris was evaded. Walking in cold weather, especially against the wind, should be avoided when possible. If feasible, the coldest month or months of the year should be spent in a warm climate.

Other activities which induce pain should be determined by a careful detailed diary kept by the patient. Such studies will teach the patient what he may do and what he should avoid, and will permit the physician to make practical suggestions. Except for walking rapidly or far, many patients will find that they can continue their gainful occupation, sometimes even when this involves certain forms of physical work such as carpentry, painting or plumbing. Sudden and unusual forms of physical exertion and hard physical labor should be interdicted.

Other precipitating factors which should be avoided are discussed below under general measures and include heavy meals, emotional outbursts, prolonged conversation, particularly on the telephone and especially on controversial subjects, straining at stool, and other activities which produce pain in individual patients. Some patients may find relaxation in playing cards, but most experience excessive emotional tension even when the stakes are small. The effect of watching competitive sports or horse racing must be carefully evaluated. Golf is permissible if the patient enjoys it and suffers no pain when playing. Caution should be exercised in the administration of insulin to patients with coronary disease, as hypoglycemia may induce an attack of angina pectoris. Similarly, epinephrine may provoke anginal pain when used diagnostically or in the treatment of bronchial asthma in patients with a diminished coronary reserve.

GENERAL MANAGEMENT

Bed rest is ordinarily not required in the treatment of angina pectoris. However, if a patient consults me promptly after his first attack of angina pectoris, I advise a period of bed rest or great limitation of activity for two weeks, for the sudden development of angina pectoris often denotes the occurrence of an acute coronary occlusion without myocardial infarction. Occasionally attacks of angina pectoris occur so frequently and with such slight bodily exertion that the patient is compelled to rest in bed. The patient should be instructed to summon his physician if the pain persists for more than fifteen minutes or if it is more intense and different from previous attacks. Although those forms of activity which induce attacks should be avoided, it is often possible for the patient to take certain forms of *exercise* or to take them at certain times of the day without discomfort. He should be encouraged to promote this muscular tone and general state of fitness by means of exercise which does not provoke pain or dyspnea.

The *psychologic approach* to the patient with angina pectoris and the *regulation and modification of his work and daily activities* are important elements in his treatment and must be carefully adjusted to individual patients. The layman is often aware that angina pectoris connotes the possibility of sudden death; therefore the term is preferably avoided entirely in a discussion of his disease. The patient's cooperation can usually be obtained if he is informed that the circulation to the heart is impaired. But it is often desirable to explain the patient's exact cardiac status and possible dangers to the patient's nearest relative. At the same time that the patient is made aware of his disability and the necessary modifications in his manner of living, he should also be assured of the probability of a long and useful life if he cooperates in treatment. Many a patient draws extraordinary optimism from the statement that cardiac patients often outlive subjects with a more favorable outlook simply because they lead a more moderate life. It is the physician's task by encouragement and ingenuity to teach the patient to adopt a philosophical attitude to his illness and to accept cheerfully the necessary adjustments in his activity and outlook.

The general questions of *occupation, hours of work, vacations,* etc., must be answered differently in individual cases according to variations in the severity and frequency of the attacks, the patient's station of life, economic status, education and skills, and the character of the underlying disease. In many hospitals, *work classification units* have been set up to aid the cardiac patient in his rehabilitation. These consist of teams of physicians, psychologists, social workers and other pertinent professional personnel who evaluate the patient and help to restore him to gainful employment.[20] Activity and gainful employment must be restricted more in patients with frequent and intractable pain on the slightest exertion than in those with occasional and mild attacks. In those with less severe disease and less frequent attacks, a careful scrutiny and analysis must be made of the patient's work and other daily activities in order to ascertain his capacity for activity and the factors which induce symptoms. His regimen must be adjusted according to the findings.

Long hours, especially when they involve continuous work under tension, must be avoided. Rest periods during the working day, especially after luncheon, are desirable when feasible; if possible also long weekends or a midweekly day of rest should be encouraged. As a rule the patient should retire early and a restful night should be assured, if necessary by the administration of soporifics before retiring or of mild sedatives during the day. In large organizations it is sometimes possible and desirable for the patient to change his job to one which is less trying, even if this transfer entails a moderate reduction in income. Sometimes it is necessary to perform only part time work and in some instances to alter the occupation completely.

Vacations are essential and, if manageable, should be taken at least twice a year. It is advantageous to take vacations during the extremes of hot and cold weather and to choose resorts in climates which avoid these extremes. On the European continent and to lesser extent in this country, patients with angina pectoris were wont to visit various spas both for treatment and for a vacation. While such visits were frequently rewarded by therapeutic benefits, these were due chiefly or entirely to the pleasant surroundings and the surcease from business and domestic stress rather than to any specific curative properties of mineral waters or baths. The well regulated regimen as to diet, exercise, bowel habits and sleep is more likely to be followed in the environment of a spa than at home or even in an ordinary resort. However, the relaxation and change of environment which are usually associated with a vacation in any pleasant surroundings are of sufficient value and are often preferable to a long inconvenient and usually expensive trip to some famous spa. Because of the reduction in oxygen tension at high altitudes, vacations in mountainous regions far above sea level are undesirable, at least theoretically, but I have known patients who have done well at places like Colorado Springs which has an altitude of 7000 feet. Similarly there is a theoretical objection to airplane travel which is usually at 5000 to 10 000 feet, and especially to stratospheric or substratospheric flying in transcontinental trips, but most commercial planes are adequately pressurized; if not, oxygen should be used when flights are made at heights exceeding 7500 feet, but especially above 10 000 feet. Most patients with angina pectoris tolerate usual commercial flights.

Diet There is no specific dietary treatment for patients with angina pectoris except a low fat diet designed to inhibit an underlying coronary atherosclerosis. The diet often depends on associated factors. In general a low calorie diet is desirable especially if the patient is overweight. It is particularly advisable to divide the dietary intake into small meals which may be taken more frequently than the usual three times daily. In the presence of associated biliary tract disease or a peptic ulcer appropriate dietary measures should be instituted. Functional gastrointestinal disturbances characterized by flatulence, postprandial distention and gaseous eructation should be treated by a bland diet (low in roughage, elimination of raw fruits, fried foods, gravies, pastries, cabbage, onions, corn and other gas producing vegetables).

Bowels Regularity of bowel habit always desirable is particularly important in these patients for colonic stasis and associated flatulence often help to produce attacks. Mild laxatives may be given if necessary. Excessive straining at stool should be avoided.

Tobacco (p 477)

Coffee and Tea These may be taken in moderate quantities. They have the theoretical advantage of being coronary vasodilators and the disadvantage of provoking nervousness and sleeplessness in some patients.

Alcohol (see drug therapy below)

DRUG THERAPY

Nitrites

The nitrites which cause direct coronary vasodilatation and increase the coronary flow more than the work of the heart[66] represent the only specific medication in the relief of angina pectoris. As a rule they are used for prompt relief of the pain after the attack develops but they should also be employed prophylactically. For the latter purpose they are taken before such activities as are known by experience to produce pain. Of course whenever possible it is best to avoid both the precipitating factor which causes pain and the nitrites. Under no circumstances should the nitrites be taken to permit the patient to perform some unusual strenuous activity which is likely to cause harm.

Nitroglycerin is the drug of choice since it is cheap, convenient to take and next to amyl nitrite acts most rapidly. It is administered in tablets which the patient is instructed to dissolve under the tongue. If the tablets are not readily soluble they may be inert or their action delayed. The usual therapeutic dose is 1/100 grain but it is preferable to begin with a 1/200 grain tablet which often suffices and is less likely to induce uncomfortable side actions. Its action is noticeable in one to two minutes and continues for fifteen minutes to an hour. In most cases the relief is striking as well as prompt. Often however it may be accompanied by mild fullness, warmth or throbbing in the head. Rarely in subjects with an idiosyncrasy to the drug severe headache, faintness or even syncope may occur. Until the effects of the drug are known it is advisable for the patient to sit down or find some support when he takes nitroglycerin. If after the repeated beneficial use of nitroglycerin the patient suffers an attack of pain which does not respond to this therapy he should be instructed to cease all activity at once and call his physician. Except when it is used prophylactically nitroglycerin should not be taken for those attacks which are known to subside promptly with a brief period of rest. Since the pain will disappear rapidly and spontaneously there is no need for the patient to suffer any unpleasant side actions of the drug. Russek et al[91] reported a paradoxical unfavorable effect of nitroglycerin with respect to the exercise electrocardiogram in 10 per cent of 158 patients with coronary disease and Starr et al[104] occasionally observed a similar unfavorable effect on the ballistocardiogram. I have observed nothing of this kind with respect to its effect on clinical symptoms.

Nitroglycerin has also been made available in a sustained action tablet termed *nitroglyn* for oral (not sublingual) use containing 1/25 or 1/10 grain and designed to be released uniformly for a period of 10 to 12 hours. A tablet at breakfast and bedtime is said to prevent or greatly diminish attacks of angina pectoris. In contrast to the unequivocal effectiveness of sublingually administered nitroglycerin, Nitroglyn is inconstantly effective but the drug in 1/10 grain dosage appears to be beneficial in some patients.

Amyl nitrite introduced by Lauder Brunton[15] in 1867 acts more rapidly (in ten to fifteen seconds) but its action lasts only for several minutes. It is administered in small glass pearls or ampules which must be

crushed in a handkerchief and inhaled Its disadvantages are its expense, inconvenience in carrying and administration and the distinctive odor which calls undesired attention to the patient when it is taken in the presence of others Its unpleasant side actions are similar to those of nitroglycerin

Other nitrites are rarely used or indicated *Sodium nitrite* administered orally in tablet form, in doses of 0 03 to 0 06 gram (½ to 1 grain) requires ten to fifteen minutes for an effect which continues for an hour or longer

Long Acting Nitrates Long acting nitrates are designed to provide the coronary vasodilator effect of the nitrites but for a prolonged sustained period When these drugs are given throughout the day it is hoped that anginal attacks can be prevented or at least reduced in number and severity The action of these nitrates is dependent on the continued release of nitrites *Erythrol tetranitrate*, which may be given orally as tablets in doses of 0 015 to 0 030 gram (¼ to ½ grain) requires fifteen minutes for effect, the duration of which is several hours Similarly *mannitol hexanitrate* and *mannitol pentanitrate*, the action of which is even more delayed and prolonged may be given in ¼ to ½ grain doses for prophylactic effect

Peritrate (pentaerythritol tetranitrate) is a long acting nitrate available in 10 mg tablets, and is administered in doses of one or two tablets three or four times daily The prophylactic action is said to begin 1½ hours after a dose and to last 4 to 5 hours It is contraindicated in glaucoma as are all the other nitrates Side effects include occasional headache and nausea which may disappear after continued administration weakness, palpitation flushing and mild hypotension Rarely a dermatitis results from drug intolerance

Very favorable claims have been made for this long acting nitrate Among 258 patients treated by Dailheu Geoffroy[22] with 60 mg daily in divided doses over 80 per cent showed a good result in contrast with only 33 per cent improvement with other coronary vasodilators Winsor and Humphreys[121] reported that Peritrate in an average daily dosage of 30 mg (range 10 to 60 mg) reduced attacks of angina pectoris in 125 patients by an average of 78 4 per cent whereas no reduction in the number of attacks was effected in 125 patients used as controls and given placebos, aminophylline (6 gm daily orally), khellin (60 mg daily) or Theocalcin (1 5 gm daily) In addition, Peritrate was said to reduce significantly the requirement for nitroglycerin, increase exercise tolerance and like nitroglycerin, reduce or prevent the electrocardiographic RS T depressions induced by exercise[90, 93] Similar favorable observations were reported by other investigators but it is of importance to note that few, if any, patients who required nitroglycerin were able to dispense with its use entirely by taking Peritrate

Despite these optimistic reports, I have not found that Peritrate (or other long acting nitrate compounds) is a valuable addition to the therapy of angina pectoris, or that it has given sufficiently consistent benefit to justify its recommendation Recently Kalman on et al,[50] using the double blind method failed to demonstrate any beneficial effects of Peritrate on angina pectoris in 23 patients The variable course of angina pectoris, the spontaneous variations in the number of attacks and in the physiologic and environmental factors which precipitate them, and especially the importance of emotional influences render evaluation of drug therapy extremely difficult in angina pectoris Therefore, unless the effectiveness of a drug is unequivocal like that of nitroglycerin, or unless it can eliminate the need for nitroglycerin it is probably of little or no value in controlling the attacks of pain

Triethanolamine trinitrate (Methamine), administered in doses of 2 mg four times daily, was reported to benefit patients with angina pectoris but Friend et al[35] found this drug to be no better than a placebo, as has been my own experience

Xanthines

Members of the xanthine group of drugs, usually compounds of theobromine or theophylline have been widely employed in cases of angina pectoris due to coronary disease despite considerable doubt as to their clinical effectiveness Their use is based on experimental observations indicating that these drugs produce coronary vasodilatation and an increased coronary flow in isolated perfused hearts heart-lung preparations or in the intact animal However, when the dosage of drug administered and the amount and transiency of increased flow are considered it is questionable whether these experimental

observations form an adequate basis for anticipating clinical benefit in human cases of angina pectoris Controlled studies in patients with angina pectoris have not confirmed the claims of clinical benefit from the xanthine drugs in angina pectoris I have virtually discontinued their use for angina pectoris except in a few patients who are convinced of their value

Aminophylline is used most frequently but its absorption is poor or inconstant when administered orally and gastrointestinal distress is caused with adequate dosage Recently choline theophyllinate, in doses of 0 2 to 1 0 gm four times daily has been reported to give relief and to control the anginal syndrome in 29 of 32 patients with angina pectoris[4] This preparation was said to be better absorbed and give higher blood levels than equivalent amounts of aminophylline and yet nausea or diarrhea occurred in only 7 3 per cent of the cases A highly favorable report of the effectiveness of choline theophyllinate was made also by Aravanis[2] Despite these favorable reports the value of the drug requires further confirmation before it can be recommended Other xanthine derivatives used and their dosage include

- Theobromine and sodium acetate—0 5 to 1 0 gm four times daily
- Theocalcin (theobromine-calcium salicylate)—0 5 to 1 0 gm four times daily
- Aminophylline (theophylline ethylenediamine)—0 1 to 0 2 gm three or four times daily

Many of the xanthine drugs have been marketed in combination with sedatives usually with phenobarbital The chief disadvantage is the rigidity imposed on the relative dosage of the two components in particular the dose of phenobarbital often needs to be altered for different patients and even for the same patient at different times The advantage is that the sedative may assure the benefit of at least one drug in the combination

Sedatives

Sedatives are among the most widely prescribed drugs in the treatment of angina pectoris Their purpose is to allay anxiety and minimize the emotional reactions which may precipitate attacks of pain *Phenobarbital* in doses of 0 015 to 0 03 gm (¼ to ½ grain) three times daily is employed most frequently sometimes in combination with a xanthine derivative *Bromides* in doses of 0 3 to 1 0 gm (5 to 15 grains) and *chloral hydrate* in 0 3 gm (5 grain) doses alone or in combination three times daily are among other sedatives often administered It is often necessary to prescribe soporifics for sleeplessness e g Seconal 0 1 to 0 2 gm (1½ to 3 grains), Nembutal 1½ to 3 grains, or Veronal 0 3 to 0 6 gm (5 to 10 grains) on retiring Opiates are not indicated in the treatment of angina pectoris because the recurrence of attacks would tend to lead to addiction If pain is persistent and unrelieved by nitrites the probability of myocardial infarction or some other cause should be considered

Recently the so-called *ataractic or tranquilizing drugs* have been administered instead of the established sedatives Miltown or Equanil in doses of 200 to 400 mg three times daily or reserpine 0 25 mg one to three times daily has been most commonly employed Their benefit in angina pectoris applies only indirectly insofar as they serve to reduce emotional tension See also chlorpromazine (Thorazine) on page 489

Other Drugs

Alcohol is often prescribed in ½ to 1 oz doses both for the prevention and relief of attacks It is the oldest drug used for this purpose since its benefits were mentioned in Heberden s original description It is doubtful that alcohol has any direct value in the prevention or alleviation of the anginal paroxysms[103] However in dogs production of a blood alcohol level comparable to that which is present in man after consuming two or three cocktails caused marked increases in coronary arterial inflow and coronary sinus outflow[54] Although I always permit and sometimes advise the ingestion of moderate amounts of alcohol by patients with angina pectoris especially elderly patients I do so more for its beneficial effect on general well being than for any dramatic improvement in the angina pectoris itself On the other hand I have seen many patients who have been made worse by an overenthusiastic indulgence in alcohol This applies particularly to patients with peptic ulcer irritable spastic colon or other gastrointestinal disturbance and those with symptoms of prostatic obstruction

Trichlorethylene has been employed for the relief and prevention of attacks of angina pectoris[63] It is administered by inhalation

three inhalations being taken after crushing a glass ampule containing 1 cc of the drug. Any beneficial effect is not dependent on coronary vasodilatation but on its anesthetic, analgesic or sedative action. Occasionally it may cause a brief loss of consciousness.

Digitalis is not indicated in the treatment of angina pectoris unless heart failure or atrial fibrillation is present. Some of the nocturnal attacks of angina pectoris occurring when the patient is recumbent, are due in part or entirely to left ventricular failure. These may be alleviated by digitalization, rigid sodium restriction, the administration of aminophylline 0.25 gm. intravenously or 0.5 gm. by rectal suppository before the patient retires, and by the use of mercurial diuretics.

Heparin has been reported to have a startlingly beneficial effect on angina pectoris[37] (see p. 422 for effect of heparin on serum lipids). According to Graham et al.[37] when heparin was given once or twice weekly in doses of 50 to 100 mg. intravenously or intramuscularly, there was a marked reduction in the number of attacks of angina pectoris in 55 of 59 patients. In my experience the administration of heparin sodium according to the same dosage schedule has not been of significant benefit in the control of anginal pain even though occasional patients reported improvement. Most recent reports indicate that heparin is not a useful therapeutic agent in angina pectoris.[8, 35, 41, 53]

Quinidine has been suggested as a therapeutic agent in the treatment of angina pectoris and Riseman et al.[86] found that quinine sulfate in doses of 0.3 to 0.4 gm. every 8 hours, is the drug of choice when the cinchona alkaloids are used in the treatment of angina pectoris. I have not found them of value. Proger and his associates[79] reported that quinidine exerted a beneficial effect on angina pectoris when attacks were precipitated or increased in frequency by a cardiac irregularity.

Papaverine has been recommended in oral doses of 0.1 gm. four times daily on the basis of its coronary vasodilator effect in animals and its sedative action.[27] However, reevaluation of the drug in doses up to 300 mg. by some of its early advocates, using new groups of patients, failed to disclose any benefit in angina pectoris.[102] These conflicting reports by the same observers form an important commentary on the evaluation of drugs in angina pectoris.

Dioxylene phosphate (Paveril phosphate) is a synthetic preparation related to papaverine with a similar action in relaxing smooth muscle and promoting coronary flow, but with less toxicity. Despite reports by a number of observers of clinical improvement in patients with angina pectoris[65, 88] when the drug was given in doses of 0.2 to 0.4 gm., I have found Paveril to be of no significant value and no longer use it. Nausea, abdominal cramps, dizziness, sweating and flushing, although relatively mild, were among some of the complaints of patients receiving the medication.

Ethaverine (diquinol), like dioxylene phosphate, is an analogue of papaverine which has the advantage of a slower onset and more prolonged action in dilating the coronary arteries in dogs. However, its administration to patients with angina pectoris in doses of 400 mg. was no more effective than that of lactose[1] or other placebos.[103]

Khellin, an extract of seeds from an Eastern Mediterranean plant, long used as an antispasmodic for ureteral colic, was recently found to be a potent bronchodilator and coronary vasodilator. Favorable results in the treatment of angina pectoris were first reported when the drug was injected intramuscularly in 100 mg. doses or given orally in 50 to 100 mg. doses three times daily.[1]

Khellin is available in 20 mg. and 40 mg. enteric coated tablets (Ammivin, Eskel, Visammin) for oral use, and has been recommended in initial doses of 20 or 40 mg. per day. This was increased each week by a daily increment of 20 or 40 mg. so long as no unpleasant side effects occurred. Otherwise the dosage was decreased or the drug withdrawn for two or three days and reinstituted at a lower dosage level. Daily doses of 200 mg. have been given, but even 50 to 100 mg. daily is not usually well tolerated. Often after a therapeutic effect only maintenance doses of 20 to 40 mg. daily were administered.

Reports in this country indicated that Visammin (khellin) effected a good or excellent therapeutic response in 35 to 90 per cent of cases of angina pectoris.[73, 90] The most common side effects are anorexia, nervousness, nausea, dizziness, weakness and depression but also vertigo, headache, diarrhea and insomnia. In my experience khellin was either ineffective in the treatment of angina

pectoris in all but occasional patients or it was impossible to give it in high enough dosage without eliciting intolerable side-effects Despite numerous previous favorable reports Greiner and associates[52] and Hultgren and associates[43] who made a study for the Council on Pharmacy of the American Medical Association found that khellin did not have any significant value in the treatment of angina pectoris It is possible that some of the favorable reports indicating a reduction in attacks of angina pectoris with khellin were due to the toxicity of the drug which necessitated limitation of activity or even bed rest Time and usage have apparently convinced the practicing physician of the ineffectiveness of khellin because I now rarely hear of its use

Testosterone Favorable results have been reported by a number of observers[57] but not by Levine and Likoff[53] In the light of recent studies of the effect of gonadal hormones on lipid metabolism (p 427) there is a theoretical contraindication to the use of androgens

The claims that vitamin E (alpha tocopherol) has therapeutic merit in cases of angina pectoris and other forms of heart disease have not been confirmed[54] This applies also to claims for tetraethylammonium chloride (TEAC) administered intramuscularly[46]

The iodides are still widely prescribed for angina pectoris but except in cases due to syphilitic ostial stenosis there is no sound basis for their usefulness in this condition Epinephrine ephedrine and other sympathomimetic drugs should not be given

Physiotherapy and balneotherapy have been used in the treatment of angina pectoris especially at various spas There is no acceptable evidence of their specific value or of the value of diathermy to the chest wall Roentgen ray therapy to the adrenals has been used to diminish acute discharges of epinephrine ■ There is insufficient evidence to recommend its employment

INDUCED MYXEDEMA BY THIOURACIL OR RADIOIODINE

Antithyroid drugs (thiourea derivatives) have been administered in order to reduce the patient's metabolism and thereby diminish the work of the heart and its need for coronary blood flow Numerous reports have appeared of improvement in persons with angina pectoris following the use of thiouracil[60] propylthiouracil[112] and methylthiouracil The disadvantages of these drugs including toxicity need for close supervision and prolonged treatment and temporary effect have also been documented

Radioiodine

The desired degree of hypothyroidism is more satisfactorily attained by the aid of radioactive iodine (I^{131}) Usually three oral doses each 20 millicuries or less are given at weekly intervals Thereafter additional single doses are given at one- to two-month intervals until hypothyroidism is manifest within two to six months after initiating treatment

Favorable results in the treatment of angina pectoris with I^{131} have been reported by Blumgart and associates[4] Wolferth et al[3] and Jaffe et al[44] and others Jaffe et al reported excellent results in 56 per cent and good results in 37 per cent of 94 patients with angina pectoris treated with radioactive iodine Blumgart et al presented the results of I^{131} treatment of 1070 euthyroid patients with advanced cardiac disease including 87 of their own and 983 reported through the cooperation of 49 other clinics Approximately 75 per cent of 720 of these patients with angina pectoris showed worth while improvement (half showed marked improvement and half a good result) The best results appeared to be obtained when the disease was relatively stable or only slightly progressive On the other hand I^{131} treatment was regarded as contraindicated when there was a recent onset of angina pectoris status anginosus or other evidence of rapidly progressive cardiovascular disease although practice in this regard is not uniform in all clinics Small daily doses (6–30 mg) of thyroid were usually administered after the I^{131} to maintain the lowest metabolic rate consistent with comfort usually minus 20 to minus 25 per cent

I have observed a number of impressive results in both patients with angina pectoris and those with severe left ventricular failure but chiefly the former Nevertheless I am skeptical that the procedure is consistently effective and that the reported benefits can be credited to the postulated rationale of the treatment Probably as with reported benefits to angina pectoris from a variety of drugs and operative procedures the results following radioiodine treatment are due to better

collateral management of the patient, enthusiasm and encouragement of the investigator, psychic factors concerned in angina pectoris, and to the variable course of the disease itself independent of treatment

The production of myxedema even when controlled by the use of thyroid extract, must be regarded as a drastic measure in the treatment of angina pectoris and can only be justified in so called intractable angina pectoris after all other medical measures and patience have been exhausted This denotes that it will be indicated in only occasional instances The simplicity of the treatment and the absence of dangerous complications render it preferable to surgical operations in these cases Furthermore, it can be made available to patients with angina pectoris and heart failure as well as other very ill patients who would be too poor risks for the surgical procedures

PARAVERTEBRAL ALCOHOL INJECTIONS

In a small percentage of cases of angina pectoris the attacks recur with such frequency and the relief from multiple daily doses of the nitrites is so transient and incomplete that it is sometimes necessary to resort to opiates For such cases, excellent results have sometimes been obtained by paravertebral alcohol injections which block the painful impulses from the heart However, the disadvantages of this treatment and the availability of other forms of therapy for intractable angina pectoris have cast the procedure of paravertebral alcohol block into relative disuse

The points at which anesthesia is effected are the upper five or six thoracic sympathetic ganglia and their adjacent rami communicantes through which the painful impulses eventually pass (see p 450) In some patients referred pains may still be experienced in the region of the ear and lower jaw and these may be abolished by injection of the mandibular nerve [6]

Satisfactory results have been reported by Levy and Moore[60] in 15 patients and by J C White and Bland[117] in 75 patients Good results with virtually complete relief of pain were obtained in 56 per cent of the latter series, a reduction in the severity of pain in 21 per cent and no appreciable result in 8 per cent Although many of these patients were extremely ill there was a mortality of only 8 per cent within two weeks of the procedure In 40 cases there was no recurrence for periods up to nine years but in 14 pain reappeared within two and one half months to five years

The advantage of the procedure is the ability to perform it without a general anesthetic and with minimal discomfort to the patient and only slight risk However, there is need for practice and skill, in 10 to 20 per cent of the attempts, a successful nerve block is not obtained The most common complication is a painful intercostal neuritis due to the alcohol injected It usually clears in a few months but may be more persistent and so severe that the posterior nerve roots must be sectioned Occasionally there is accidental injury to the pleura with consequent pleuritis pleural effusion or pneumothorax and rarely injury to the spinal cord structures

The *technique of paravertebral alcohol injection* as described by White and Smithwick[118] and by Levy and Moore[60] is as follows
